Abstract: Several recent studies have documented that reactions between melt and crystal mush in primitive gabbroic rocks (via reactive porous flow) have an important control in the formation of the lower oceanic crust and the evolution of MORBs. In this context, olivine-rich rocks can form either by fractional crystallization of primitive melts or by open system reactive percolation of pre-existing (possibly mantle-derived) olivine matrix. To address this question, we performed in-situ trace element analyses (by LA-ICP-MS) of olivine from the Erro-Tobbio ophiolite Unit (Ligurian Alps), where mantle peridotites show gradational contacts with an hectometer-scale body of troctolites and plagioclase wehrlites, and both are cut by later decameter-wide lenses and dykes of olivine gabbros. Previous studies inferred that troctolites and olivine gabbros represent variably differentiated crystallization products from primitive MORB-type melts. Olivines in the three rock types (mantle peridotites, troctolites, olivine gabbros) exhibit distinct geochemical signature and well-defined elemental correlations. As expected, compatible elements (e.g. Ni) show the highest concentrations in peridotites (2580-2730 ppm), intermediate in troctolites (2050-2230 ppm) and lowest in gabbros (1355-1420 ppm), whereas moderate incompatible elements (e.g. Mn, Zn) show the opposite behaviour. By contrast, highly incompatible elements like Zr, Hf, Ti, HREE are variably enriched in olivines of troctolites, and the enrichment in absolute concentrations is coupled to development of significant HFSE/REE fractionation (ZrN/NdN up to 80). AFC modeling shows that such large ZrN/NdN ratios in olivines are consistent with a process of olivine assimilation and plagioclase crystallization at decreasing melt mass, in agreement with textural observations. In-situ trace element geochemistry of olivine, combined with microstructural investigations, thus appears a powerful tool to investigate reactive percolation and the origin of olivine-rich rocks in the lower oceanic crust.

43 Abstract

Several recent studies have documented that reactions between melt and crystal mush in primitive gabbroic rocks (via reactive porous flow) have an important control in the formation of the lower oceanic crust and the evolution of MORBs. In this context, olivine-rich rocks can form either by fractional crystallization of primitive melts or by open system reactive percolation of pre-existing (possibly mantle-derived) olivine matrix. To address this question, we performed in-situ trace element analyses (by LA-ICP-MS) of olivine from the Erro-Tobbio ophiolite Unit (Ligurian Alps), where mantle peridotites show gradational contacts with an hectometer-scale body of troctolites and plagioclase wehrlites, and both are cut by later decameter-wide lenses and dykes of olivine gabbros. Previous studies inferred that troctolites and olivine gabbros represent variably differentiated crystallization products from primitive MORB-type melts. Olivines in the three rock types (mantle peridotites, troctolites, olivine gabbros) exhibit distinct geochemical signature and well-defined elemental correlations. As expected, compatible elements (e.g. Ni) show the highest concentrations in peridotites (2580-2730 ppm), intermediate in troctolites (2050-2230 ppm) and lowest in gabbros (1355-1420 ppm), whereas moderate incompatible elements (e.g. Mn, Zn) show the opposite behaviour. By contrast, highly incompatible elements like Zr, Hf, Ti, HREE are variably enriched in olivines of troctolites, and the enrichment in absolute concentrations is coupled to development of significant HFSE/REE fractionation (Zr_N/Nd_N up to 80). AFC modeling shows that such large Zr_N/Nd_N ratios in olivines are consistent with a process of olivine assimilation and plagioclase crystallization at decreasing melt mass, in agreement with textural observations. In-situ trace element geochemistry of olivine, combined with microstructural investigations, thus appears a powerful tool to investigate reactive percolation and the origin of olivine-rich rocks in the lower oceanic crust.

83 1. INTRODUCTION

84 Several lines of evidence have stressed that melt/rock reactions acting at the oceanic mantlecrust boundary play an important role in the chemical evolution of MORBs and the formation of the 85 86 primitive (olivine-rich) lower oceanic crust (Bedard et al., 2000; Coogan et al., 2000; Drouin et al., 87 2009, 2010; Gao et al., 2007; Dick et al., 2008; Lissenberg and Dick, 2008; Kvassnes and Grove, 88 2008; Eason and Sinton, 2009; Godard et al., 2009; Collier and Kelemen, 2010; Renna and 89 Tribuzio, 2011; Sanfilippo and Tribuzio, 2011, 2012; Lissenberg et al., 2013; Sanfilippo et al., 90 2013, 2014, 2015a,b; Saper and Liang 2014). Specific chemical features in MORBs, such as the 91 spread in MgO contents at given CaO values, cannot be easily reconciled with processes of 92 fractional crystallization of heterogeneous parental melts occurring at variable pressure. Based on 93 this observation, a series of papers inferred that the composition of MORBs can be modified by 94 melt/rock reactions taking place either in the primitive lower oceanic crust, or in the uppermost 95 lithospheric mantle (e.g. Lissenberg and Dick, 2008; Collier and Kelemen, 2010; Lissenberg et al., 96 2013). Collier and Kelemen (2010) described this process as reactive crystallization, linking the 97 peculiar chemical signatures of MORBs to the diffuse evidence of melt percolation and 98 impregnation in the oceanic mantle (e.g. Dick, 1989; Cannat et al., 1990; Rampone et al., 1997, 99 2008; Godard et al., 2000; Tartarotti et al., 2002; Dijkstra et al., 2003; Niu, 2004; Chazot et al., 100 2005; Piccardo et al. 2007; Kelemen et al., 2007; Müntener et al., 2010).

101 Parallel chemical and microstructural studies on olivine-rich intrusive rocks (troctolites, 102 werhlites, olivine gabbros) from modern ridge settings and ophiolites (Lissenberg and Dick, 2008; Drouin et al., 2009, 2010; Renna and Tribuzio, 2011; Sanfilippo and Tribuzio, 2011, 2012; 103 104 Lissenberg et al., 2013; Sanfilippo et al., 2013, 2014, 2015a,b) have suggested a composite "hybrid" 105 origin of these rocks, likely related to open-system melt impregnation of an olivine crystal 106 framework. An open issue thus concerns the origin of oceanic troctolites, whether they formed by 107 fractional crystallization of primitive melts or by reactive percolation of pre-existing (possibly 108 mantle-derived) olivine matrix.

109 Olivine is an ubiquitous mineral in both mantle and primitive lower crustal rocks, and 110 largely involved in melt/rock reaction processes. Consequently, it has become increasingly 111 important to improve knowledge about its trace element composition, and to test the existence of 112 geochemical signatures to distinguish a magmatic versus a mantle origin. Foley et al. (2013) 113 proposed a large compilation of trace element data in olivine from mantle peridotites and 114 Mediterranean volcanics. They outlined the great potential of olivine as a petrogenetic tracer of 115 mantle melting and early igneous crystallization, and the need of further studies on natural olivines, 116 in order to improve the current database, lacking many promising elements.

117 Many studies have been devoted to determining diffusion and partition coefficients for 118 minor and trace elements in olivine (e.g. Irving, 1978; Shimizu et al., 1982; Kinzler et al., 1990; 119 Beattie (1994); Dunn and Sen, 1994; Eggins et al., 1998; Taura et al., 1998; Gregoire et al., 2000; 120 Petry et al., 2004; Zanetti et al., 2004; Bedard, 2005; Coogan et al., 2005; Witt-Eickschen and 121 O'Neill, 2005; Holzapfel et al., 2007; Lee et al., 2007; Spandler et al., 2007; Brady and Cherniak, 122 2010; Chakraborty, 2010; Cherniak, 2010; Dohmen et al., 2010; Spandler and O'Neill, 2010; 123 Cherniak and Watson, 2012; Burgess and Cooper, 2013; Girona and Costa, 2013; Cherniak and 124 Liang, 2014; Cherniak and Van Orman, 2014; Jolland et al., 2014; Kennedy et al., 1993; Zhukova et 125 al., 2014), and a very robust data set exists on selected minor element abundances (e.g. Ni, Co, Mn, Cr) of olivine phenochrysts in basalts from different tectonic environments (Sobolev et al., 2005, 126 127 2007; Foley et al., 2013). Other studies have determined selected minor, trace elements concentrations in mantle olivines (e.g. O'Reilly et al., 1997; Normann, 1998; see also the data 128 129 compilations in De Hoog et al., 2010, Foley et al., 2013). However, only a few studies provide a 130 complete set of trace element compositions measured in olivine from mantle peridotite (Sun and Kerrick, 1995; Eggins et al., 1998; Bedini and Bodinier, 1999; Garrido et al., 2000; Gregoire et al., 131 132 2000; De Hoog et al., 2010) and gabbroic rocks (Drouin et al., 2009; Sanfilippo et al., 2014). This is mostly due to the difficulty to get reliable analyses, due to the extremely low abundances of many 133 134 trace elements (e.g. REE, Ti, Zr, Hf) in this mineral.

We have selected peridotite, troctolite and gabbro samples from the ophiolitic Erro-Tobbio 135 136 Unit (Ligurian Alps, Italy; Borghini et al., 2007, Borghini and Rampone, 2008), and performed a set 137 of in-situ trace element analyses (by LA-ICP-MS) on olivine in both mantle and crustal rocks, with 138 the objective to provide a first "baseline" dataset on olivine trace element chemistry in associated 139 rocks of different origins (mantle and magmatic), and to exploit the potential of olivine 140 geochemistry to get insights into processes of reactive melt percolation at the oceanic 141 peridotite/gabbro transition. A major outcome of this work is that olivine in most of the troctolites 142 has unexpected trace element compositions, indicative of melt/rock reactions likely involving 143 concomitant olivine dissolution and plagioclase crystallization. Furthermore, discrepancies between 144 the compositions of melts in equilibrium with olivine and coexisting minerals, in both mantle and 145 gabbroic rocks, point to the need for a better understanding of the mechanisms of incorporation and 146 diffusion of trace elements in olivine.

147

148 2. FIELD RELATIONS AND SAMPLES

The Erro-Tobbio Unit (ET, Voltri Massif, Ligurian Alps, Italy, Fig. 1) consists of predominant mantle peridotites, intruded by discrete gabbroic bodies and dykes, and represent remnants of the Jurassic Ligurian Tethys oceanic lithosphere. These rocks, in spite of the Alpine 152 overprint, preserve kilometre-scale structural and chemical records of their pre-Alpine evolution

(Bezzi and Piccardo, 1971; Chiesa et al., 1975; Ernst and Piccardo, 1979; Ottonello et al., 1979;
Piccardo et al., 1990; 1992; Hoogerdujin Strating et al., 1990; 1993; Vissers et al., 1991; Borsi et

155 al., 1996; Capponi et al., 1999; Piccardo et al., 2004; Rampone et al., 2004, 2005).

The extension-related exhumation of the Erro-Tobbio mantle from deep lithospheric depths (P > 15-20 kbar) to a shallow level (P < 5 kbar) was accompanied by a composite history of melt migration and intrusion marked by i) open-system melt migration and reactive porous flow at spinel-facies depths, ii) melt/rock reaction at shallower and colder lithospheric level, leading to the formation of plagioclase-enriched impregnated peridotites, iii) multiple gabbroic intrusions (Piccardo et al., 2004; Rampone et al., 2004, 2005; Piccardo and Vissers, 2007; Borghini et al., 2007; Borghini and Rampone, 2007; Rampone and Borghini, 2008).

163 Samples investigated in this work were collected in the Southern sector of the Erro Tobbio 164 Unit (Fig. 1), where plagioclase-rich impregnated peridotites are intruded by a discrete hundred-165 metre-scale magmatic body, mostly consisting of troctolites, and minor plagioclase-bearing dunites 166 and wehrlites. This compositional variability often defines a magmatic layering. The contact 167 between host mantle rocks and troctolites is gradational, in places marked by troctolite and wehrlite apophyses within the peridotites (Fig. 2a). Inside the troctolite body, the layering is also defined by 168 169 a textural variability of olivine, ranging from granular to harrisitic (Fig. 2 b,c,d), with skeletal 170 olivine crystals up to dm-scale size. Similar textures have been already documented in ophiolites 171 and in layered intrusions (e.g. O'Driscoll et al., 2007; Renna and Tribuzio, 2011), and interpreted as 172 primary magmatic disequilibrium texture related to open-system episodic melt influx. Subsequent 173 olivine-gabbro lenses and thin dykelets intruded both peridotites and troctolites, crosscutting the 174 peridotite foliation and the magmatic layering in the troctolite body (Borghini et al., 2007).

175 The studied samples are two peridotites (MF40, P1), five troctolites (MF21, MF51, MF72Ga, MF72Ha, MF73Ga) and one olivine gabbro (MF22). Samples MF22, MF40, MF21, 176 177 MF51 were studied earlier (Borghini et al. 2007; Borghini and Rampone, 2007; Rampone et al., 178 2014) for major and trace element mineral chemistry (olivine and associated pyroxenes and 179 plagioclase). Based on their bulk and mineral chemical compositions, troctolites and olivine 180 gabbros were interpreted as crystallization products of variably evolved N-MORB-type melts 181 (Borghini et al., 2007). The N-MORB affinity of parental melts is also indicated by Nd isotopic composition of gabbros (average initial ε_{Nd} of 9.25 ± 0.25; Rampone et al., 2014). A brief summary 182 183 of salient petrographic and chemical characteristics of these samples is given below. The new 184 samples included in this study are three troctolites showing variable olivine texture, from granular 185 (MF72Ga, MF73Ga) to harrisitic (MF72Ha), and one mantle peridotite (P1). Troctolites MF72Ga 186 and MF72Ha represent different textural domains in one single sample (MF72).

Peridotites (MF40, P1) are low-strain spinel tectonites showing diffuse plagioclase enrichment related to melt impregnation. This is illustrated by reactive dissolution and replacement of clinopyroxene by orthopyroxene + plagioclase intergrowth, and reactive dissolution of kinked mantle olivine by poikilitic orthopyroxene (see Borghini et al., 2007).

191 Troctolites (MF21, MF51, MF72Ga, MF73Ga) are made of dominant subidiomorphic 192 granular olivine, idiomorphic Cr-spinel, interstitial plagioclase and subordinate clinopyroxene (Fig. 193 3a). They also contain small interstitial accessory minerals (Ti-rich pargasitic amphibole, ilmenite, 194 orthopyroxene) as thin rims around Cr-rich spinel and olivine, related to late-stage crystallization of 195 small fractions of trapped melt (Borghini and Rampone, 2007). The interstitial clinopyroxene and plagioclase often show lobate contacts against olivine, indicative of partial olivine resorption. 196 197 Reactive dissolution of olivine is even more evident in the coarse-grained harrisitic types (MF73H, 198 MF72Ha), where cm-size hopper olivine crystals are significantly corroded by plagioclase 199 crystallization (Fig. 3c). In the troctolite apophysis MF51, olivine occurs either as euhedral 200 undeformed crystals, or as large and irregular kinked grains, partly resorbed by plagioclase (Fig. 201 3b).

Olivine gabbro MF22 displays coarse- to medium-grained hypidiomorphic texture, with euhedral to subhedral olivine (about 10% by vol.), euhedral to subhedral plagioclase and anhedral to poikilitic clinopyroxene (Fig. 3d). The crystallization sequence, olivine–plagioclase–clinopyroxene, is typical of low-P oceanic gabbros. Olivine mostly exhibits rather regular contacts against plagioclase and clinopyroxene.

207

208 3. ANALYTICAL METHODS

The major element compositions of minerals in most of studied samples were provided in previous papers (Borghini et al., 2007; Borghini and Rampone, 2007). Here we report complementary analyses (in addition to data for the new samples P1, MF72Ga, MF72Ha, MF73Ga) for all mineral spots analysed in-situ for trace element chemistry.

Major element compositions of minerals were analysed using a JEOL JXA 8200 Superprobe equipped with five wavelength-dispersive (WDS) spectrometers, an energy dispersive (EDS) spectrometer, and a cathodoluminescence detector (accelerating potential 15 kV, beam current 15 nA), operating at the Dipartimento di Scienze della Terra, University of Milano.

In situ trace element compositions were determined by LA-ICPMS at Géosciences Montpellier (AETE, University of Montpellier, France). Plagioclase, clinopyroxene, orthopyroxene and olivine were analyzed using 120 μm thick polished sections. Sites of analysis were carefully selected optically to discard those affected by alteration. Analysed trace elements (and corresponding m/z values) were: ⁷Li, ¹¹B, ⁴⁵Sc, ⁴⁷Ti, ⁵¹V, ⁵⁵Mn, ⁵⁹Co, ⁶²Ni, ⁶⁶Zn, ⁸⁸Sr, ⁸⁹Y, ⁹⁰Zr,

⁹³Nb, ¹³⁷Ba, rare earth elements (REEs: ¹³⁹La, ¹⁴⁰Ce, ¹⁴¹Pr, ¹⁴⁶Nd, ¹⁴⁷Sm, ¹⁵¹Eu, ¹⁵⁷Gd, ¹⁵⁹Tb, ¹⁶³Dy, 222 ¹⁶⁵Ho, ¹⁶⁷Er, ¹⁶⁹Tm, ¹⁷³Yb, ¹⁷⁵Lu), ¹⁷⁷Hf, ¹⁸¹Ta, ²⁰⁸Pb, ²³²Th and ²³⁸U. Analyses were performed with 223 a Thermo Scientific Element XR (eXtended Range) high resolution ICPMS. The ICP-MS was 224 225 coupled to a laser ablation system consisting of a Geolas (Microlas) automated platform with a 193 226 nm Excimer Compex 102 laser from LambdaPhysik. Ablation analyses were performed using an inhouse modified 30 cm³ ablation cell with a helium atmosphere to enhance sensitivity and reduce 227 228 inter-element fractionation (Günther and Heinrich, 1999). Helium gas and ablated sample material 229 were mixed with argon gas before entering the plasma. The laser energy density was set to 12 J cm^{-2} at a frequency of 8 Hz and the beam size was set to 102 $\mu m.$ Data were collected in time 230 resolved acquisition mode, with the background signal collected for 2 min followed by 1 min of 231 232 sample ablation.

233 Data were reduced with the GLITTER software package (Van Achterberg et al., 2001), 234 using the linear fit to ratio method. Data were filtered for spikes on an element by element basis. Internal standardization relative to EPMA data was done using ²⁹Si for all minerals. Detection limits 235 236 were <1 ppb for most highly incompatible elements except for Ba, Zr and Sr (<2 ppb); they were 237 <15 ppb for Sb, V, Cu, Zn, Co, Sc, Li and B and <200 ppb for Mn, Ti and Ni (Supplementary 238 Table 1). Values that were within 1σ of the detection limit were excluded during data reduction. Data reported in Tables 1, 2, 3 are single-spot analyses, whereas averages of trace element 239 240 compositions in olivine for each sample (data in Figures 6 and 7) are reported in Supplementary 241 Table 2). Supplementary Table 3 reports 1σ error values of olivine analyses reported in Table 1. A 242 typical time series for the analysis of trace elements in olivine is reported in the Supplementary 243 Note 1. Instrument sensitivity due to analytical conditions was determined from the average across 244 all days of repeat measurements of the synthetic NIST 612 glass (Pearce et al., 1997). Sensitivities 245 were 800 cps/ppm for Ni, 2000-4000 cps/ppm for Ti, B and Zn, 6000-15000 cps/ppm for Li, Cu, 246 Sb, Ba, Nd, Sm, Gd, Dy, Yb and Pb and >20000 cps/ppm for all other elements. Precision and 247 accuracy were constrained by 8 analyses of reference basalt BIR 1-G (Supplementary Table 1): 248 reproducibility was better than 5% for most elements except for Pb (16%), B and Ta (<10%) and 249 measured values were comparable within analytical uncertainties to GEOREM accepted values 250 (Jochum et al., 2005).

251

252 4. MAJOR AND TRACE ELEMENT MINERAL CHEMISTRY

253 Major and trace element compositions of olivine, plagioclase, clinopyroxene and 254 orthopyroxene are shown in Tables 1, 2, 3. In most analysed olivines, we observed acceptable 255 correlations between the Ni, Mn and Ca abundances analysed by EPMA and LA-ICPMS (see 256 Supplementary Figure 1). Overall, the major and trace element chemistry data that are reported here for clinopyroxene and plagioclase in samples MF22, MF40, MF21, MF51 are similar to previously
published datasets (Borghini et al., 2007).

259

260 **4.1. Peridotites**

Olivines in peridotites have forsterite contents ranging Fo₈₉-Fo₉₀. They display the highest 261 Ni (2570-2725 ppm) coupled to the lowest Mn (1170-1210 ppm), Zn (56-61 ppm), Hf, Ti and Li 262 263 abundances, of all investigated (peridotite-troctolite-gabbro) samples (Figs. 4, 5, 6). REE patterns 264 define regular trends for the H- (heavy) REE, but tend to be more disperse for the M- (middle) and 265 especially the L- (light) REE (Fig.7). They show strong MREE/HREE fractionation ($Tb_N/Yb_N =$ 0.004-0.042, normalized to C1-chondrite of Sun and McDonough, 1989), more pronounced than in 266 267 the majority of available literature data on trace element chemistry of mantle olivines in orogenic 268 massifs and xenoliths (see compositional field and references reported in Figure 7). However, 269 published data mostly refer to metasomatized peridotites, as indicated by their enrichment in LREE 270 and other highly incompatible elements (see fields in Figures 7c, 8c). Note also that all previous 271 data are bulk analyses of olivine separates, thus possibly incorporating trace elements hosted in 272 inclusions. On the other hand, D'Errico et al., 2015 recently documented similar MREE/HREE 273 fractionation in olivine from Gakkel Ridge peridotites (see the compositional field in Figures 7c, 274 8c).

275 Plagioclase in peridotites is fully replaced by low-grade alteration products. Clinopyroxenes 276 are partly dissolved and replaced by (orthopyroxene + plagioclase) intergrowths crystallized from 277 the infiltrating melts. Their major and trace element compositions (Figs. 7,8 and Table 3) are 278 consistent with previously published data (Borghini et al., 2007). Melt-rock interaction has 279 modified their trace element composition (Borghini et al., 2007), causing an overall REE increase 280 (M- to H-REE up to > 10xC1, see Fig. 7a), coupled to Zr, Y, Sc, V enrichment and strong Sr 281 depletion (see Fig. 8a), compared to clinopyroxenes in those Erro-Tobbio spinel peridotites that 282 represent the mantle protolith before melt impregnation (Rampone et al., 2004; 2005). Similar 283 changes in clinopyroxene composition have been largely documented in plagioclase-rich 284 impregnated peridotites of the Alpine-Apennine system (Rampone et al., 1997, 2008; Piccardo et al., 2004; Zanetti et al., 2007). They are interpreted as resulting from the combined effects of 285 286 equilibration with enriched melts modified during reactive percolation at decreasing melt mass, and 287 crystallization of small trapped melt fractions. In spite of the overall REE increase, clinopyroxenes 288 preserve marked LREE depletion ($La_N/Yb_N = 0.008-0.016$), more pronounced than in 289 clinopyroxenes from troctolites and gabbros (see Figure 7a). On this basis, Borghini et al. (2007) 290 and Rampone and Borghini (2008) inferred that melt impregnation in the Erro-Tobbio peridotites was caused by reactive porous flow of orthopyroxene-saturated depleted MORB-type melts,unrelated to subsequent intrusion of N-MORB-type magmas.

The analyzed orthopyroxenes represent melt-rock reaction products, crystallized together with plagioclase and replacing mantle clinopyroxene (see description above). They display low REE abundances (M-, H-REE below 2-3x C1, Fig. 7a), significant LREE/HREE fractionation ($Ce_N/Yb_N = 0.003-0.005$), and negative Sr and Eu anomalies coupled to Zr and Hf enrichment relative to the neighbouring REE (Fig. 8a).

298

299 **4.2. Troctolites and Gabbro**

300 Olivines from troctolites have high forsterite contents (Fo₈₈-Fo₈₉). The lowest forsterite 301 values (Fo₈₈) are observed in samples with variable (granular and harrisitic) texture. They also 302 display relatively high Ni (2050-2280 ppm), Mn (1010-1625 ppm) and moderate Zn (45-70 ppm) 303 contents (see Fig. 4,5). The Co abundances are more scattered, and similar to those of olivines in 304 peridotites. Troctolite olivines display a negative correlation between Mg# (Mg/(Mg+Fe)) and Mn 305 content (Fig. 4b), with the lowest Mg# and highest Mn values observed in the composite granular-306 harrisitic samples. As expected, olivines in gabbro MF22 have the lowest forsterite contents (Fo₈₃-307 Fo₈₄), combined with the lowest Ni (1355-1415 ppm) and higher Mn (1890-1970 ppm), Zn (93-102 308 ppm) and Co (165-170 ppm) abundances. For all these elements (i.e. Mn, Zn, Co, Ni), troctolite 309 olivines show intermediate concentrations compared to those of olivines in peridotites and gabbro. 310 In contrast, their Hf, Ti and Zr concentrations are more variable (progressive enrichment), and 311 extend beyond those of olivines in the gabbro (Figs. 6,7). Li abundances show the same behaviour, 312 although the data are slightly more scattered (see Fig. 6d). Olivines in troctolites also exhibit the 313 highest REE contents (HREE up to 0.8-1xC1, Fig. 7c), coupled to strong MREE/HREE 314 fractionation ($Tb_N/Yb_N = 0.004-0.042$) and development of significant positive Zr-Hf anomalies 315 relative to the neighbouring REE (Fig. 8c). Drouin et al. (2009) documented similar REE 316 compositions in olivine from Mid Atlantic Ridge (MAR) olivine-rich troctolites (see the grey field 317 in Fig. 8c).

Plagioclases in the studied troctolites and gabbro have similar anorthite contents (An_{58-63} in troctolites, An_{62} in gabbro, see Table 2). In the troctolites, the lowest anorthite values (An_{58-59}) are observed in composite granular-harrisite samples. Overall, plagioclases display LREE-enriched REE patterns ($La_N/Sm_N = 1.23-2.56$, Fig. 7a), positive Sr and Eu anomalies, and strong negative Zr-Hf anomalies relative to the neighbouring REE (Fig. 8b). In gabbro MF22, plagioclases exhibit the lowest REE abundances (LREE < 1 x C1), whereas in troctolites they show a larger LREE variability, with LREE up to 4xC1 in plagioclases of composite granular-harrisite troctolites (Fig. 325 7a). Similar REE compositions were documented by Borghini et al. (2007) (see the grey field in326 Fig. 7b).

327 The major and trace element compositions of clinopyroxenes reported in Table 3 were 328 measured in cores of large crystals. For the purpose of this study, we did not consider within-crystal 329 major-trace element variations related to late-stage crystallization of interstitial trapped melts. The 330 reader can refer to Borghini and Rampone (2007) for this specific issue. Troctolite clinopyroxenes 331 have high Mg# (0.89-0.90) coupled to relatively Al_2O_3 (3.04-4.82 wt%), Na_2O (0.43-0.61 wt%) and 332 Cr₂O₃ (1.02-1.50 wt%) concentrations (Table 3), similar to those of clinopyroxenes from oceanic 333 and ophiolitic troctolites (Drouin et al., 2009; Sanfilippo and Tribuzio, 2012). Lower Mg# (0.86) and Al₂O₃, Cr₂O₃ contents are found in clinopyroxenes of gabbro MF22. Overall, clinopyroxenes 334 335 display moderate LREE depletion ($La_N/Sm_N = 0.11-0.14$ in troctolites and gabbro) and almost flat 336 MREE to HREE patterns. As described above for plagioclase, gabbro clinopyroxenes have the 337 lowest REE abundances (M-H-REE below 10 x C1, Fig.7a), whereas troctolite clinopyroxenes 338 exhibit a general REE increase (M-H-REE up to 20 x C1) at nearly constant LREE fractionation 339 (Fig. 7a). The REE increase is coupled to the development of negative Eu and Sr anomalies relative 340 to neighbouring REE (Fig. 8a).

341

342 **5. DISCUSSION**

343 **5.1. Mineral/mineral REE partitioning**

A number of studies have shown that the distribution of trace elements between olivine, orthopyroxene and clinopyroxene depends on temperature, pressure and mineral compositions (e.g. Witt-Eickschen et al., 2005; Lee et al., 2007; Sun and Liang, 2012, 2013, 2014). For REE, the effect of decreasing temperature is to redistribute these elements into clinopyroxene, thus lowering the olivine/clinopyroxene and orthopyroxene/clinopyroxene partition coefficients. Also, this effect is stronger for the LREE relative to the HREE, possibly resulting in significant changes of the LREE/HREE fractionation in low-T (< 1000 °C) re-equilibrated minerals (Sun and Liang, 2014).

Lee et al. (2007) predicted Ol/Cpx and Opx/Cpx REE partition coefficients at variable 351 352 temperatures based on lattice strain theory. Sun and Liang (2014) developed parameterized lattice 353 strain models for REE and Y distribution among mantle minerals in a wide range of T conditions 354 (800-1300°C), using mineral/melt partitioning models calibrated against experimentally determined 355 mineral/melt partition coefficients (Sun and Liang, 2012, 2013). In order to test the distribution of 356 REE between olivine, clinopyroxene and orthopyroxene in the Erro-Tobbio peridotites, troctolites 357 and gabbro, and derive information about equilibration temperatures, we computed Ol/Cpx and Opx/Cpx REE partition coefficients in our samples, and compared them with i) predicted trends by 358 359 Lee et al. (2007) (Fig. 9), ii) computed olivine/cpx trends, according to Sun and Liang (2012, 2013, 360 2014) modeling. This approach allows to calculate Ol/Cpx partition coefficients at varying T for a 361 specific sample, using proper major element mineral compositions (Fig. 10; see figure caption for 362 more details). The two sets of modelled temperature contours, shown in Figures 9 and 10, are 363 similar, with a modest shift at higher Ol/Cpx partitioning values, at a given T, of trends computed 364 according to Sun and Liang (2014) (see Figs. 9a and 10).

In all samples, Ol/Cpx partition coefficients regularly decrease from Lu to Dy, whereas they 365 366 tend to define concave trends from MREE to LREE (Figs. 9a, 10). Similar "U-shaped" Ol/Cpx 367 partitioning was already documented in previous studies (e.g. Agranier and Lee, 2007; Lee et al., 368 2007) and was ascribed to the difficulty to get accurate analyses of LREE in olivine, due to the extremely low concentrations in these elements, and/or to the occurrence of LREE-bearing fluid 369 370 inclusions. However, it is remarkable that the Ol/Cpx partition coefficients for Gd, Eu and Nd in 371 most samples are consistent with predicted trends (see Figs. 9a and 10), pointing to the reliability of 372 our olivine data set for the majority of REE. Overall, the Ol/Cpx H- to M-REE distribution in most 373 investigated samples defines arrays that are slightly steeper than computed trends. As already 374 outlined in the results section, this is likely a consequence of the strong MREE/HREE fractionation 375 shown by olivines in this study, more pronounced than the large majority of published data. Except 376 for Dy and Tb, most Ol/Cpx partitioning data for the HREE indicate rather high equilibration 377 temperatures (> 1100 °C). The highest values are observed in the troctolites, relative to peridotites 378 and gabbro, and are probably related to the high HREE concentrations in olivines of troctolites 379 resulting from melt/rock reaction processes (see the discussion below)

In Figure 9b, we also show the Opx/Cpx REE distribution coefficients for the two peridotite samples, compared with modelled trends by Lee et al. (2007). They define almost linear arrays, monotonically decreasing from HREE to LREE. Remarkably, these trends are mostly consistent with predicted Opx/Cpx partitioning at high temperature (> 1300 °C). In these samples, high-T estimates (1350-1400 °C) were also obtained by the REE in two-pyroxene thermometer of Liang et al (2013).

In summary, mineral/mineral REE partitioning in the Erro-Tobbio samples are mostly indicative of high temperature of equilibration (> 1100-1200 °C). Accordingly, we infer that the REE concentrations in olivine, clinopyroxene and orthopyroxene were not significantly modified by subsolidus re-equilibration, hence potentially recording information about the chemical signature of equilibrium melts. Nevertheless, the possible effect of decreasing temperature on olivine/clinopyroxene REE re-distribution is further discussed in the following section.

392

393 5.2. Paradoxical chemical signatures in olivine

The comparison of olivine compositions in the three investigated rock types, peridotite, troctolite and gabbro reveals both expected and unexpected behaviour for trace elements.

Remarkably, olivines in the three rock types exhibit distinct geochemical signature and define systematic elemental correlations for a series of minor (Ni, Mn) and trace elements (Zn, Co, Ti, Zr, Hf, HREE). Similar correlations (at least for Ni, Mn, Ti, Zr, Yb) have been documented by Sanfilippo et al. (2013) in a study of troctolites and mantle peridotites from the Alpine ophiolites (see data reported in Figs. 4,5,6). These data provide the evidence that olivine, although being a very minor reservoir for many trace elements, can record magmatic processes.

402 As expected, highly compatible elements in olivine such as Ni (Lee et al., 2007; Spandler et 403 al., 2010, and references therein) show the highest contents in peridotite, intermediate in troctolite 404 and lowest in gabbro, whereas Mn, Zn and Co show the opposite behaviour. Data on the 405 partitioning of Mn, Zn and Co in olivine (Ehlers et al., 1992; Kennedy et al., 1993; Beattie, 1994; 406 Gaetani and Grove, 1997; Kohn and Schofield, 1994; Bedard, 2005; Mysen, 2007; Spandler and 407 O'Neill, 2010) indicate a moderately incompatible to compatible behaviour. De Hoog et al. (2010), 408 in a comprehensive study of the trace element composition of mantle olivines from different origins 409 and settings, found negative correlations between Mn, Zn abundances and forsterite contents, thus 410 confirming their moderately incompatible behaviour. They also documented little systematic variation of Co with forsterite values, indicative of a $K_D^{ol/melt}$ very close to 1. In our study, the 411 412 overall increase of Mn, Zn and Co abundances in olivines from mantle peridotites to gabbro further 413 demonstrate a moderately incompatible behaviour of these elements. Moreover, in the Mg# versus 414 Ni diagram of Figure 4a, the compositional array defined by the Erro-Tobbio peridotite-troctolite-415 gabbro olivines is roughly consistent with computed trends for fractional crystallization at low 416 pressure (< 5 Kb) of a primary MORB melt (e.g. Drouin et al., 2009; grey lines in Fig. 4a). In 417 addition, Mn and Ni abundances of troctolite olivines fall within the compositional field defined by 418 MORB phenocrysts (see Figs. 4a,b; data from Sobolev et al., 2007). These features are in agreement 419 with previous inference by Borghini et al. (2007) that troctolites and gabbros reflect crystallization 420 products of variably evolved MORB magmas.

421 Zr, Hf, Ti and HREE display unforeseen behaviours. The concentrations of these elements 422 in troctolite olivines define enrichment trends that start from abundances similar to those in gabbro 423 olivines, and go up to one order of magnitude higher values (Fig. 6). These elements are all highly 424 incompatible in olivine (Lee et al., 2007; Spandler and O'Neill, 2010; De Hoog et al., 2010; and 425 references therein). If the composition of olivine in troctolites and gabbros were simply reflecting 426 fractionation from a variably evolved melt, we would expect the highest contents in incompatible 427 elements in the gabbro olivines. Moreover, the HREE enrichment in troctolite olivine is coupled to 428 the development of pronounced Zr-Hf positive anomalies and Zr/Nd fractionation (Zr_N/Nd_N up to 429 100). The same selective Zr-Hf enrichment was described in olivines from oceanic troctolites by 430 Drouin et al. (2009). All these features indicate that the behaviour of these elements in the studied 431 olivine data set does not conform to a simple magmatic crystallization process, and melt/rock 432 reaction processes likely have occurred (see the discussion section below).

Another unexpected chemical characteristic in olivine is its ubiquitous (even in the gabbro) depleted REE composition (Fig. 7c). Similar REE patterns were documented by Drouin et al. (2009) in olivines from oceanic troctolites. These authors observed that computed melts in equilibrium with such olivines are significantly more depleted than melts in equilibrium with associated plagioclase and clinopyroxene. Hence, they proposed that the trace element depleted signature of olivine in the troctolites could reflect a mantle origin, whereas plagioclase and clinopyroxene crystallized from impregnating MORB-type melts.

440 The REE composition of melts computed in equilibrium with olivine, clinopyroxene, 441 orthopyroxene and plagioclase from the Erro-Tobbio peridotites, troctolites and gabbro are shown 442 in Figure 11. Following Drouin et al. (2009), melts were computed using clinopyroxene/liquid, 443 orthopyroxene/liquid, and olivine/liquid partition coefficients from Lee et al. (2007), and 444 plagioclase/liquid partition coefficients from Aigner-Torres et al. (2007). As previously documented 445 by Drouin et al. (2009), computed melts in equilibrium with olivine in all investigated lithotypes 446 exhibit lower REE abundances than melts in equilibrium with clinopyroxene. An exception to this 447 behaviour is provided by Yb, which shows similar values in most computed melts (Fig. 11a,b,c). In 448 troctolites, melts in equilibrium with plagioclase and clinopyroxenes display large variation in 449 absolute REE contents, related to late-stage crystallization of interstitial melts (Borghini and 450 Rampone, 2007). In spite of such variation, computed melts exhibit similar composition, with 451 nearly flat REE patterns, indicative of a MORB affinity (Borghini et al., 2007). In contrast, melts in 452 equilibrium with olivine display strong MREE/HREE fractionation ($Dy_N/Yb_N = 0.17-0.39$). 453 Although such decoupling in the troctolites could reflect a different origin between olivine (possibly 454 mantle derived) and associated plagioclase/clinopyroxene, this can be ruled out in gabbro MF22 (Fig. 11c), for which microstructural and major-minor element chemical features of olivine (and 455 456 field relations) clearly indicate a magmatic origin.

In order to test whether the adopted partition coefficients could have a role in generating such contrasting signature, we also calculated the equilibrium melts using the following sets of partition coefficients: i) the compilation proposed in Bedard (2001), derived on the basis of empirical relationships between ln(Kd) and composition, and adopted by Lissenberg et al. (2013) to model reactive melt migration in the lower oceanic crust of Hess Deep (EPR), ii) the olivine/melt and clinopyroxene/melt partition coefficients computed for our samples at T = 1200 °C, according to Sun and Liang (2012, 2013) mineral/melt REE partitioning models. The resulting REE 464 compositions of equilibrium melts are reported in Figures 12 and 13. In spite of differences in 465 absolute concentrations, we observed the same decoupling between the M-H-REE composition of 466 melts in equilibrium with plagioclase and clinopyroxene, and those in equilibrium with olivine, the 467 latter being even more fractionated ($Dy_N/Yb_N = 0.043-0.098$) when using the Bedard (2001) Kds. 468 Finally, in order to check whether the observed decoupling of equilibrium melts compositions could 469 be related to subsolidus redistribution of REE between olivine and clinopyroxene at lower 470 temperature, we computed apparent melt compositions using the Kds sets obtained at 1100°C, by 471 using Sun and Liang (2012,2013) models. The results are shown in Supplementary Figure 2. Again, 472 the major effect is a difference in absolute concentrations, with a general shift at lower REE 473 contents of computed melts in equilibrium with clinopyroxene, and higher REE abundances of 474 computed melts in equilibrium with olivine. On the other hand, the decoupling of M-H-REE 475 composition in clinopyroxene and olivine equilibrium melts largely persists, although the latter are 476 slightly less fractionated ($Dy_N/Yb_N = 0.13-0.29$ at 1200°C, and 0.15-0.34 at 1100 °C). Therefore, 477 re-distribution of REE between olivine and other minerals at subsolidus conditions is not sufficient 478 to explain the observed decoupling.

A robust explanation of such chemical discrepancies between melts computed in equilibrium with olivine and those in equilibrium with all other minerals is presently lacking, and possibly lies in the inhibited incorporation of REE into the olivine crystal lattice, due to their high ionic radius relative to the M1 and M2 sites dimensions (Zanetti et al., 2004; Foley et al., 2013). This, in turn, can explain the uncertainties and variability of available partition and diffusion coefficients for REE and other highly incompatible elements in olivine.

485 Available experimental studies on the diffusion of trace elements in olivine have provided 486 contrasting results. Spandler et al. (2007) and Spandler and O'Neill (2010) documented fast re-487 equilibration of REE in olivine, at rates similar to Mg-Fe exchange. By contrast, Cherniak (2010) 488 and Remmert et al. (2008) found much lower (more than three order of magnitude) REE diffusion 489 coefficients. They showed that REE diffusion in olivine is faster than in orthopyroxene and 490 clinopyroxene, but slow enough to preserve REE heterogeneities in melt inclusions in olivine 491 phenocrysts, at time scales of geologic processes. Cherniak (2010) also documented similar 492 diffusivities for M- and H-REE (La, Dy, Yb), indicating no correlation between REE diffusion 493 coefficients and ionic radius (consistent with Spandler and O'Neill, 2010), and little dependence of 494 REE diffusion rates on crystallographic orientation. This behaviour differs from the pronounced 495 anisotropy (more rapid diffusion parallel to c axis) documented for Fe-Mg and many trace elements 496 (e.g. Ni, Cr, Zr, Hf) in olivine (Chakraborty, 1997; Petry et al., 2004; Ito and Ganguly, 2006; 497 Spandler and O'Neill, 2010; Jollands et al., 2014).

498 More recently, Burgess and Cooper (2013) explained the discrepancies between the results 499 of Cherniak (2010) and Spandler and O'Neill (2010) as a consequence of different diffusion 500 mechanisms acting in olivine, with "lattice diffusion" in the former, and "fast-path diffusion" 501 promoted by formation of extended defects, in the latter. Specifically, Burgess and Cooper (2013), 502 in a combined experimental-TEM study on olivine in equilibrium with a TiO_2 -rich MORB (similar 503 to that used by Spandler and O'Neill, 2010), showed that the nucleation and growth of planar 504 defects in olivine is enhanced by large TiO₂ chemical potential gradients at the olivine-melt boundary (leading to substitution of Ti⁴⁺ for divalent cations in the olivine octahedral site, and 505 formation of octahedral vacancies). These authors outlined the need for a re-evaluation of the 506 507 "simple" lattice diffusion mechanism, especially in the case of natural reacting systems governed by 508 significant chemical potential gradients (e.g. metasomatism or magma mixing), and the importance 509 of detailed analysis of natural and experimental samples for a better understanding of trace element 510 diffusion in olivine.

In spite of such contrasting results, all studies provide consistent evidence of similar 511 512 diffusion coefficients in olivine from HREE to LREE. Therefore, the ubiquitous strong 513 MREE/HREE fractionation observed in all the analysed olivines cannot be easily related to 514 modifications of the REE profile acquired by subsolidus diffusion and re-equilibration, as a 515 consequence of different M- to H-REE diffusion rates. On the other hand, the large variation of 516 available partition coefficients for REE (one to two orders of magnitude, especially for the LREE 517 and MREE; see Bedard, 2001; Lee et al., 2007; Spandler and O'Neill, 2010) indicates the difficulty 518 to get reliable values, and sheds light on the caution that is needed in using olivine REE contents to 519 derive information about the compositions of equilibrum melts. The main factors influencing the 520 REE partitioning between olivine and melt have been discussed in a series of papers. Bedard (2005) examined published natural and experimental ^{olivine/liquid}D, and found a general tendency to increase 521 522 with decreasing temperature and MgO content in the melt. Evans et al. (2008), in an experimental 523 study in the CMAS system, documented strong inverse correlation between olivine-melt partition 524 coefficients and SiO₂ contents in melt. Finally, Sun and Liang (2013), through the development of 525 parameterized lattice strain models, found that the primary variables determining the REE and Y 526 partitioning between olivine and melt are pressure, Forsterite and Al contents in olivine.

527 Overall, the results of our study further emphasize the need of enlarging the trace element 528 olivine data set in natural mantle and gabbroic samples, as well as the importance of parallel 529 experimental work. Based on present knowledge, the REE composition of olivine cannot be easily 530 adopted to discriminate between mantle versus magmatic origin. Nevertheless, the peculiar and 531 systematic trace element signature documented in olivine of troctolites points to a more complex 532 origin than a simple fractional crystallization.

534 **5.3. Evidence of melt/rock reaction in troctolites**

535 The studied troctolites show microstructural and chemical evidence of mineral/melt reaction 536 and disequilibrium. In most samples, olivine displays irregular and lobate contacts against 537 interstitial minerals (plagioclase and subordinate clinopyroxene) indicative of reactive dissolution 538 and resorbtion. Reactive dissolution of olivine is even more evident in coarse-grained harrisitic 539 troctolites (e.g. sample MF72Ha), where centimetre-size hopper olivine crystals are significantly 540 corroded by plagioclase crystallization (Fig. 3c). Similar granular to hopper to harrisitic textures in 541 olivine are described in the literature in layered intrusions and ophiolites (e.g. Donaldson et al., 542 1982; O'Driscoll et al., 2007; Renna and Tribuzio, 2011), and are considered to result from open-543 system processes causing variations in melt composition and, consequently, in the degree of 544 undercooling (e.g. Faure et al., 2003). Moreover, in the troctolite apophysis MF51 olivine occurs 545 both as euhedral crystals and as large and irregular kinked grains, partly resorbed by plagioclase 546 (Fig. 3b). All these features point to disequilibrium and reaction between the olivine framework (at 547 least part of it) and the melt that crystallized the interstitial minerals.

548 Specific chemical characteristics also provide the same information. As outlined by 549 Borghini et al. (2007), the overall major element compositions of minerals in Erro-Tobbio 550 troctolites and gabbros define a variational trend at rather low An contents in plagioclase at given 551 Fo in olivine and Mg# of clinopyroxene, as observed in some gabbroic rock suites from the Mid-552 Atlantic Ridge (e.g. Ross and Elton, 1997). Troctolites, specifically, display variable An contents in 553 plagioclase at rather constant Fo value in olivine. The new troctolite samples analysed in this study with granular to harrisitic textures further confirm the lack of Fo-An correlation in the troctolites, 554 555 being characterized by very low An values in plagioclase (An₅₈₋₅₉) at high Fo contents in olivine 556 (Fo_{87.5-88.5}) and high Mg# in clinopyroxene (100*Mg# = 88-89.8)(see Tables 1,2,3). Although part 557 of such chemical features, namely the low An contents in plagioclase and high Mg# in 558 clinopyroxene, can be ascribed to crystallization at moderate P conditions (3-5 kbar, see Borghini et 559 al., 2007), the large compositional range defined by plagioclase in the troctolites (An₅₈₋₆₆; Borghini 560 et al 2007 and this study) at rather constant olivine composition rules out a simple process of 561 fractional crystallization. This in turn calls for melt-rock reaction processes, in which exotic input of 562 more evolved melts in a previously crystallized olivine framework, and/or crystallization of 563 intercumulus liquid evolving upon cooling and partially trapped within the crystal mush, could have 564 played a role.

565 Both textural and mineral chemistry features in the Erro-Tobbio troctolites thus point to 566 melt-rock reaction involving olivine dissolution and concomitant plagioclase crystallization. In 567 order to test, with a simple but effective approach, whether the observed trace element variations and geochemical signature in olivine of troctolites, namely the selective HFSE (Zr, Hf, Ti) and
HREE enrichment, can be explained by such process, we performed an Assimilation Fractional
Crystallization (AFC) model (using the equation of De Paolo, 1981), assuming the following
reaction:

572

$olivine_1 + melt_1 = olivine_2 + plagioclase + melt_2$,

573 in which "olivine₂" represents the olivine reequilibrated with the reacted melt₂. For clarity, we 574 emphasize that in this study we were not able to distinguish two olivine generations in a specific 575 troctolite sample, both in terms of textural occurrence and chemical composition. We often 576 observed corroded olivine grains that texturally represent the "olivine₁" of the above reaction, but 577 possess geochemical characteristics of "olivine₂". We further discuss this point below.

578 The results of AFC modeling are shown in Figure 14, in terms of Zr_N/Nd_N versus Yb_N in 579 olivine computed in equilibrium with the reacted melt₂ (i.e. olivine₂). A major difficulty in 580 performing geochemical modeling is the choice of appropriate mineral/liquid partition coefficients. This is especially crucial in the case of olivine and plagioclase, for which complete mineral/liquid D sets 581 582 including REE and HFSE are poorly available in literature (see discussion above). We thus 583 performed two distinct AFC models (Models A and B of Fig.14a,b), keeping fixed all the 584 parameters except the partition coefficients, in order to highlight the variability of computed trends 585 resulting from the choice of D values. In both models, the assimilated mass (Ma) is equal to 100% olivine, whereas the crystallized mass (Mc) is 100% plagioclase. The composition of the starting 586 587 melt (C_0 , reacting with olivine₁) is equal to the melt computed in equilibrium with the troctolite 588 clinopyroxene showing the lowest REE concentrations (i.e. clinopyroxene in sample MF21; see 589 Figs. 7a, 8a). This melt is very similar (at least for the L- and M- REE) to the composition of melt 590 computed in equilibrium with troctolite plagioclase with the lowest REE abundances (i.e. 591 plagioclase in sample MF51, see Figs. 7b, 8b), and we considered it as the best proxy of the 592 composition of the interstitial melt before reactive crystallization. For the assimilated olivine, we 593 used the composition of olivine in peridotite MF40, showing the lowest Yb and HFSE 594 concentrations among all the investigated data set. It is remarkable, however, that olivine in gabbro 595 MF22 also show low Zr_N/Nd_N fractionation and REE (see Figs. 7c, 8c), being likely less affected by 596 melt-rock reaction processes than the troctolites. As clearly shown in Figure 14, the two (peridotite and gabbro) olivine compositions almost overlap. Therefore, using the gabbro olivine as Ma would 597 598 have produced the same results discussed below.

599 Computed trends reported in Figure 14 show the compositions of olivine in equilibrium with 600 residual liquids (melt₂) at decreasing melt mass (F = 0.95-0.10). The four different trends refer to 601 different values of r (where r is equal to the Ma/Mc ratio). The models A and B (Fig. 14a,b) differ 602 only in terms of adopted partition coefficients (see figure caption for details and references). 603 Keeping in mind the uncertainties resulting from the adopted parameters (partition coefficients, 604 composition of initial melt C_0 and assimilated olivine Ma), and the very simplified approach, the 605 model clearly suggests that the observed enrichment in Zr in olivine of the troctolites can be 606 explained by a melt-rock reaction process involving dissolution of olivine and crystallization of 607 plagioclase (in almost equal amounts, best consistency with Ma/Mc = 0.95) at progressively decreasing melt mass. This is due to the fact that olivine has higher ^{mineral/liquid}D_{Zr,Hf} relative to 608 609 plagioclase, consistent with the significant Zr-Hf negative anomalies in plagioclase compositions, especially in plagioclase of gabbro MF22 (see Fig. 8b). This behaviour of olivine, i.e. olivine/liquid 610 D_{HFSE} > $^{olivine/liquid}$ D_{REE} , has been invoked by Kelemen et al. (1990) to explain the development of 611 612 arc-like signature in basaltic melt during reactive percolation through the lithospheric mantle, and it 613 has been confirmed by the study of Bedard (2005), who highlighted the ubiquitous presence of 614 positive D_{Ti,Zr,Hf} anomalies in experimental olivine/melt partitioning data for a wide range of 615 basaltic compositions.

616 As mentioned above, there is an apparent decoupling between the reaction considered in the 617 AFC model, and our textural and geochemical observations. The reaction involves an olivine₁, 618 likely possessing a higher forsterite content and low incompatible trace element abundances, and an 619 olivine₂, supposed to crystallized from the reacted melt. However, in our study troctolite olivines 620 which are significantly resorbed by plagioclase (i.e. texturally representing olivine₁), have enriched 621 trace element signature, i.e. that expected for olivine₂. This could be explained assuming that 622 olivine₁ has reset its composition, by interaction with the melt, rather than crystallizing in new 623 grains.

624 In this study, we aimed to provide a first trace element data set in olivine from associated 625 peridotite, troctolite and gabbro samples, in order to document major geochemical differences, if 626 any, between the different rock types, and test the potential of trace element chemistry in olivine to 627 track melt-rock reaction processes. Therefore, we did not focus the analytical work to detect within-628 grain elemental variations. The results of this study clearly indicate that the troctolites hold a more 629 complex magmatic history than previously documented (Borghini et al., 2007; Borghini and 630 Rampone, 2007). Borghini and Rampone (2007) found significant trace element zoning in poikilitic 631 clinopyroxenes, correlated with the microstructural site (e.g. core to rims of large crystals, to very 632 thin interstitial grains). They ascribed this feature to late-stage crystallization of interstitial trapped 633 melts, and assumed olivine dissolution to explain the development of positive Zr, Hf anomalies in 634 the very late-stage clinopyroxene. Here we show that olivine records the geochemical signature of 635 such melt-mineral reaction. Detailed microstructural and geochemical investigations, involving Crystallographic Preferred Orientation (CPO) analyses (e.g. Drouin et al., 2010) combined to 636 637 major-trace element traverses and mapping in selected olivine grains, will be essential to check the

existence of different generations of olivine within a single troctolite sample, and the preservation(or absence) of major, trace element zoning in a specific olivine crystal.

Records of compositional zoning in minerals largely depend on element diffusion rates, 640 temperature conditions of crystallization and cooling rates. Major and minor element variations in 641 642 olivine, such as decrease in NiO, Mg# and increase in TiO₂, have been documented in experiments 643 of formation of plagioclase-bearing peridotites and wehrlites by reactive crystallization, and 644 ascribed to the effects of dissolution and reprecipitation from the basaltic melt (Saper and Liang, 645 2014). Moreover, Welsch et al. (2014) recently documented surprising dendritic zoning of 646 phosphorous in volcanic, experimental, and also plutonic olivine crystals (by electron probe microanalysis and mapping), and Burgess and Cooper (2013) shed lights on the diffusion 647 648 mechanisms in olivine by combined experimental and TEM investigations. Overall, these works 649 illustrate the usefulness of micro- and nano-scale detailed studies to get insights on combined 650 processes of olivine deformation, dissolution and growth. Textural and geochemical variability 651 documented in this study in troctolite olivines further confirms the relevance of such approaches.

652

653 6. CONCLUDING REMARKS

In-situ LA-ICP-MS analyses of a large set of trace elements in olivines of depleted mantle peridotites and associated primitive gabbroic rocks (troctolites and olivine gabbros) from the Ligurian ophiolites (Erro-Tobbio Unit, Italy) have revealed that olivines define systematic and reliable compositional trends that can be used to unravel their history of melt-rock reaction and magmatic crystallization.

659 In contrast with olivine gabbros, olivines in the troctolites display significant enrichment in 660 incompatible elements like Zr, Hf, Ti, HREE, coupled to development of significant HFSE/REE 661 fractionation. Such geochemical features are indicative of dissolution-precipitation processes and re-equilibration with reacted enriched melts. AFC modeling shows that the large Zr_N/Nd_N ratios in 662 663 olivines of troctolites are consistent with a process of olivine assimilation and plagioclase 664 crystallization at decreasing melt mass, in agreement with textural observations. Detailed in-situ 665 trace element geochemistry of olivine, possibly combined with focused microstructural analysis, 666 thus appears to be a powerful tool to investigate reactive percolation and the origin of olivine-rich 667 rocks in the lower oceanic crust.

668 Compositional contrasts between computed melts in equilibrium with olivine and coexisting 669 minerals, in both mantle peridotites and MORB-type gabbroic rocks, point to the need for a better 670 understanding of the mechanisms of incorporation and diffusion of trace elements in olivine.

671

672 ACKNOWLEDGEMENTS

We thank Andrea Risplendente (Dipartimento di Scienze della Terra, University of Milano) for his assistance with the EPMA analyses, and Carlotta Ferrando (PhD student in Montpellier) who performed part of the LA-ICP-MS analyses. J.C.M de Hoog and C. Sun are greatly acknowledged for their constructive reviews. We also thank editorial advise and handling by W. van Westrenen and M. Norman. This study was supported by the University of Genova (grant PRA 2014), and the CNRS-INSU program SYSTER.

43 Abstract

Several recent studies have documented that reactions between melt and crystal mush in primitive gabbroic rocks (via reactive porous flow) have an important control in the formation of the lower oceanic crust and the evolution of MORBs. In this context, olivine-rich rocks can form either by fractional crystallization of primitive melts or by open system reactive percolation of pre-existing (possibly mantle-derived) olivine matrix. To address this question, we performed in-situ trace element analyses (by LA-ICP-MS) of olivine from the Erro-Tobbio ophiolite Unit (Ligurian Alps), where mantle peridotites show gradational contacts with an hectometer-scale body of troctolites and plagioclase wehrlites, and both are cut by later decameter-wide lenses and dykes of olivine gabbros. Previous studies inferred that troctolites and olivine gabbros represent variably differentiated crystallization products from primitive MORB-type melts. Olivines in the three rock types (mantle peridotites, troctolites, olivine gabbros) exhibit distinct geochemical signature and well-defined elemental correlations. As expected, compatible elements (e.g. Ni) show the highest concentrations in peridotites (2580-2730 ppm), intermediate in troctolites (2050-2230 ppm) and lowest in gabbros (1355-1420 ppm), whereas moderate incompatible elements (e.g. Mn, Zn) show the opposite behaviour. By contrast, highly incompatible elements like Zr, Hf, Ti, HREE are variably enriched in olivines of troctolites, and the enrichment in absolute concentrations is coupled to development of significant HFSE/REE fractionation (Zr_N/Nd_N up to 80). AFC modeling shows that such large Zr_N/Nd_N ratios in olivines are consistent with a process of olivine assimilation and plagioclase crystallization at decreasing melt mass, in agreement with textural observations. In-situ trace element geochemistry of olivine, combined with microstructural investigations, thus appears a powerful tool to investigate reactive percolation and the origin of olivine-rich rocks in the lower oceanic crust.

83 1. INTRODUCTION

84 Several lines of evidence have stressed that melt/rock reactions acting at the oceanic mantlecrust boundary play an important role in the chemical evolution of MORBs and the formation of the 85 86 primitive (olivine-rich) lower oceanic crust (Bedard et al., 2000; Coogan et al., 2000; Drouin et al., 87 2009, 2010; Gao et al., 2007; Dick et al., 2008; Lissenberg and Dick, 2008; Kvassnes and Grove, 88 2008; Eason and Sinton, 2009; Godard et al., 2009; Collier and Kelemen, 2010; Renna and 89 Tribuzio, 2011; Sanfilippo and Tribuzio, 2011, 2012; Lissenberg et al., 2013; Sanfilippo et al., 90 2013, 2014, 2015a,b; Saper and Liang 2014). Specific chemical features in MORBs, such as the 91 spread in MgO contents at given CaO values, cannot be easily reconciled with processes of 92 fractional crystallization of heterogeneous parental melts occurring at variable pressure. Based on 93 this observation, a series of papers inferred that the composition of MORBs can be modified by 94 melt/rock reactions taking place either in the primitive lower oceanic crust, or in the uppermost 95 lithospheric mantle (e.g. Lissenberg and Dick, 2008; Collier and Kelemen, 2010; Lissenberg et al., 96 2013). Collier and Kelemen (2010) described this process as reactive crystallization, linking the 97 peculiar chemical signatures of MORBs to the diffuse evidence of melt percolation and 98 impregnation in the oceanic mantle (e.g. Dick, 1989; Cannat et al., 1990; Rampone et al., 1997, 99 2008; Godard et al., 2000; Tartarotti et al., 2002; Dijkstra et al., 2003; Niu, 2004; Chazot et al., 100 2005; Piccardo et al. 2007; Kelemen et al., 2007; Müntener et al., 2010).

101 Parallel chemical and microstructural studies on olivine-rich intrusive rocks (troctolites, 102 werhlites, olivine gabbros) from modern ridge settings and ophiolites (Lissenberg and Dick, 2008; Drouin et al., 2009, 2010; Renna and Tribuzio, 2011; Sanfilippo and Tribuzio, 2011, 2012; 103 104 Lissenberg et al., 2013; Sanfilippo et al., 2013, 2014, 2015a,b) have suggested a composite "hybrid" 105 origin of these rocks, likely related to open-system melt impregnation of an olivine crystal 106 framework. An open issue thus concerns the origin of oceanic troctolites, whether they formed by 107 fractional crystallization of primitive melts or by reactive percolation of pre-existing (possibly 108 mantle-derived) olivine matrix.

109 Olivine is an ubiquitous mineral in both mantle and primitive lower crustal rocks, and 110 largely involved in melt/rock reaction processes. Consequently, it has become increasingly 111 important to improve knowledge about its trace element composition, and to test the existence of 112 geochemical signatures to distinguish a magmatic versus a mantle origin. Foley et al. (2013) 113 proposed a large compilation of trace element data in olivine from mantle peridotites and 114 Mediterranean volcanics. They outlined the great potential of olivine as a petrogenetic tracer of 115 mantle melting and early igneous crystallization, and the need of further studies on natural olivines, 116 in order to improve the current database, lacking many promising elements.

117 Many studies have been devoted to determining diffusion and partition coefficients for 118 minor and trace elements in olivine (e.g. Irving, 1978; Shimizu et al., 1982; Kinzler et al., 1990; 119 Beattie (1994); Dunn and Sen, 1994; Eggins et al., 1998; Taura et al., 1998; Gregoire et al., 2000; 120 Petry et al., 2004; Zanetti et al., 2004; Bedard, 2005; Coogan et al., 2005; Witt-Eickschen and 121 O'Neill, 2005; Holzapfel et al., 2007; Lee et al., 2007; Spandler et al., 2007; Brady and Cherniak, 122 2010; Chakraborty, 2010; Cherniak, 2010; Dohmen et al., 2010; Spandler and O'Neill, 2010; 123 Cherniak and Watson, 2012; Burgess and Cooper, 2013; Girona and Costa, 2013; Cherniak and 124 Liang, 2014; Cherniak and Van Orman, 2014; Jolland et al., 2014; Kennedy et al., 1993; Zhukova et 125 al., 2014), and a very robust data set exists on selected minor element abundances (e.g. Ni, Co, Mn, Cr) of olivine phenochrysts in basalts from different tectonic environments (Sobolev et al., 2005, 126 127 2007; Foley et al., 2013). Other studies have determined selected minor, trace elements concentrations in mantle olivines (e.g. O'Reilly et al., 1997; Normann, 1998; see also the data 128 129 compilations in De Hoog et al., 2010, Foley et al., 2013). However, only a few studies provide a 130 complete set of trace element compositions measured in olivine from mantle peridotite (Sun and Kerrick, 1995; Eggins et al., 1998; Bedini and Bodinier, 1999; Garrido et al., 2000; Gregoire et al., 131 132 2000; De Hoog et al., 2010) and gabbroic rocks (Drouin et al., 2009; Sanfilippo et al., 2014). This is mostly due to the difficulty to get reliable analyses, due to the extremely low abundances of many 133 134 trace elements (e.g. REE, Ti, Zr, Hf) in this mineral.

We have selected peridotite, troctolite and gabbro samples from the ophiolitic Erro-Tobbio 135 136 Unit (Ligurian Alps, Italy; Borghini et al., 2007, Borghini and Rampone, 2008), and performed a set 137 of in-situ trace element analyses (by LA-ICP-MS) on olivine in both mantle and crustal rocks, with 138 the objective to provide a first "baseline" dataset on olivine trace element chemistry in associated 139 rocks of different origins (mantle and magmatic), and to exploit the potential of olivine 140 geochemistry to get insights into processes of reactive melt percolation at the oceanic peridotite/gabbro transition. A major outcome of this work is that olivine in most of the troctolites 141 142 has unexpected trace element compositions, indicative of melt/rock reactions likely involving 143 concomitant olivine dissolution and plagioclase crystallization. Furthermore, discrepancies between 144 the compositions of melts in equilibrium with olivine and coexisting minerals, in both mantle and 145 gabbroic rocks, point to the need for a better understanding of the mechanisms of incorporation and 146 diffusion of trace elements in olivine.

147

148 2. FIELD RELATIONS AND SAMPLES

The Erro-Tobbio Unit (ET, Voltri Massif, Ligurian Alps, Italy, Fig. 1) consists of predominant mantle peridotites, intruded by discrete gabbroic bodies and dykes, and represent remnants of the Jurassic Ligurian Tethys oceanic lithosphere. These rocks, in spite of the Alpine overprint, preserve kilometre-scale structural and chemical records of their pre-Alpine evolution
(Bezzi and Piccardo, 1971; Chiesa et al., 1975; Ernst and Piccardo, 1979; Ottonello et al., 1979;
Piccardo et al., 1990; 1992; Hoogerdujin Strating et al., 1990; 1993; Vissers et al., 1991; Borsi et al., 1996; Capponi et al., 1999; Piccardo et al., 2004; Rampone et al., 2004, 2005).

The extension-related exhumation of the Erro-Tobbio mantle from deep lithospheric depths (P > 15-20 kbar) to a shallow level (P < 5 kbar) was accompanied by a composite history of melt migration and intrusion marked by i) open-system melt migration and reactive porous flow at spinel-facies depths, ii) melt/rock reaction at shallower and colder lithospheric level, leading to the formation of plagioclase-enriched impregnated peridotites, iii) multiple gabbroic intrusions (Piccardo et al., 2004; Rampone et al., 2004, 2005; Piccardo and Vissers, 2007; Borghini et al., 2007; Borghini and Rampone, 2007; Rampone and Borghini, 2008).

163 Samples investigated in this work were collected in the Southern sector of the Erro Tobbio 164 Unit (Fig. 1), where plagioclase-rich impregnated peridotites are intruded by a discrete hundred-165 metre-scale magmatic body, mostly consisting of troctolites, and minor plagioclase-bearing dunites 166 and wehrlites. This compositional variability often defines a magmatic layering. The contact 167 between host mantle rocks and troctolites is gradational, in places marked by troctolite and wehrlite apophyses within the peridotites (Fig 2a). Inside the troctolite body, the layering is also defined by 168 169 a textural variability of olivine, ranging from granular to harrisitic (Fig. 2 b,c,d), with skeletal 170 olivine crystals up to dm-scale size. Similar textures have been already documented in ophiolites 171 and in layered intrusions (e.g. O'Driscoll et al., 2007; Renna and Tribuzio, 2011), and interpreted as 172 primary magmatic disequilibrium texture related to open-system episodic melt influx. Subsequent 173 olivine-gabbro lenses and thin dykelets intruded both peridotites and troctolites, crosscutting the 174 peridotite foliation and the magmatic layering in the troctolite body (Borghini et al., 2007).

175 The studied samples are two peridotites (MF40, P1), five troctolites (MF21, MF51, MF72Ga, MF72Ha, MF73Ga) and one olivine gabbro (MF22). Samples MF22, MF40, MF21, 176 177 MF51 were studied earlier (Borghini et al. 2007; Borghini and Rampone, 2007; Rampone et al., 178 2014) for major and trace element mineral chemistry (olivine and associated pyroxenes and 179 plagioclase). Based on their bulk and mineral chemical compositions, troctolites and olivine gabbros were interpreted as crystallization products of variably evolved N-MORB-type melts 180 181 (Borghini et al., 2007). The N-MORB affinity of parental melts is also indicated by Nd isotopic composition of gabbros (average initial ε_{Nd} of 9.25 ± 0.25; Rampone et al., 2014). A brief summary 182 183 of salient petrographic and chemical characteristics of these samples is given below. The new 184 samples included in this study are three troctolites showing variable olivine texture, from granular 185 (MF72Ga, MF73Ga) to harrisitic (MF72Ha), and one mantle peridotite (P1). Troctolites MF72Ga 186 and MF72Ha represent different textural domains in one single sample (MF72).
Peridotites (MF40, P1) are low-strain spinel tectonites showing diffuse plagioclase enrichment related to melt impregnation. This is illustrated by reactive dissolution and replacement of clinopyroxene by orthopyroxene + plagioclase intergrowth, and reactive dissolution of kinked mantle olivine by poikilitic orthopyroxene (see Borghini et al., 2007).

191 Troctolites (MF21, MF51, MF72Ga, MF73Ga) are made of dominant subidiomorphic 192 granular olivine, idiomorphic Cr-spinel, interstitial plagioclase and subordinate clinopyroxene (Fig. 193 3a). They also contain small interstitial accessory minerals (Ti-rich pargasitic amphibole, ilmenite, 194 orthopyroxene) as thin rims around Cr-rich spinel and olivine, related to late-stage crystallization of 195 small fractions of trapped melt (Borghini and Rampone, 2007). The interstitial clinopyroxene and plagioclase often show lobate contacts against olivine, indicative of partial olivine resorption. 196 197 Reactive dissolution of olivine is even more evident in the coarse-grained harrisitic types (MF73H, 198 MF72Ha), where cm-size hopper olivine crystals are significantly corroded by plagioclase 199 crystallization (Fig. 3c). In the troctolite apophysis MF51, olivine occurs either as euhedral 200 undeformed crystals, or as large and irregular kinked grains, partly resorbed by plagioclase (Fig. 201 3b).

Olivine gabbro MF22 displays coarse- to medium-grained hypidiomorphic texture, with euhedral to subhedral olivine (about 10% by vol.), euhedral to subhedral plagioclase and anhedral to poikilitic clinopyroxene (Fig. 3d). The crystallization sequence, olivine–plagioclase–clinopyroxene, is typical of low-P oceanic gabbros. Olivine mostly exhibits rather regular contacts against plagioclase and clinopyroxene.

207

208 3. ANALYTICAL METHODS

The major element compositions of minerals in most of studied samples were provided in previous papers (Borghini et al., 2007; Borghini and Rampone, 2007). Here we report complementary analyses (in addition to data for the new samples P1, MF72Ga, MF72Ha, MF73Ga) for all mineral spots analysed in-situ for trace element chemistry.

Major element compositions of minerals were analysed using a JEOL JXA 8200 Superprobe equipped with five wavelength-dispersive (WDS) spectrometers, an energy dispersive (EDS) spectrometer, and a cathodoluminescence detector (accelerating potential 15 kV, beam current 15 nA), operating at the Dipartimento di Scienze della Terra, University of Milano.

In situ trace element compositions were determined by LA-ICPMS at Géosciences Montpellier (AETE, University of Montpellier, France). Plagioclase, clinopyroxene, orthopyroxene and olivine were analyzed using 120 μm thick polished sections. Sites of analysis were carefully selected optically to discard those affected by alteration. Analysed trace elements (and corresponding m/z values) were: ⁷Li, ¹¹B, ⁴⁵Sc, ⁴⁷Ti, ⁵¹V, ⁵⁵Mn, ⁵⁹Co, ⁶²Ni, ⁶⁶Zn, ⁸⁸Sr, ⁸⁹Y, ⁹⁰Zr,

⁹³Nb, ¹³⁷Ba, rare earth elements (REEs: ¹³⁹La, ¹⁴⁰Ce, ¹⁴¹Pr, ¹⁴⁶Nd, ¹⁴⁷Sm, ¹⁵¹Eu, ¹⁵⁷Gd, ¹⁵⁹Tb, ¹⁶³Dy, 222 165 Ho, 167 Er, 169 Tm, 173 Yb, 175 Lu), 177 Hf, 181 Ta, 208 Pb, 232 Th and 238 U. Analyses were performed with 223 a Thermo Scientific Element XR (eXtended Range) high resolution ICPMS. The ICP-MS was 224 225 coupled to a laser ablation system consisting of a Geolas (Microlas) automated platform with a 193 226 nm Excimer Compex 102 laser from LambdaPhysik. Ablation analyses were performed using an inhouse modified 30 cm³ ablation cell with a helium atmosphere to enhance sensitivity and reduce 227 228 inter-element fractionation (Günther and Heinrich, 1999). Helium gas and ablated sample material 229 were mixed with argon gas before entering the plasma. The laser energy density was set to 12 J cm^{-2} at a frequency of 8 Hz and the beam size was set to 102 $\mu m.$ Data were collected in time 230 resolved acquisition mode, with the background signal collected for 2 min followed by 1 min of 231 232 sample ablation.

233 Data were reduced with the GLITTER software package (Van Achterberg et al., 2001), 234 using the linear fit to ratio method. Data were filtered for spikes on an element by element basis. Internal standardization relative to EPMA data was done using ²⁹Si for all minerals. Detection limits 235 236 were <1 ppb for most highly incompatible elements except for Ba, Zr and Sr (<2 ppb); they were 237 <15 ppb for Sb, V, Cu, Zn, Co, Sc, Li and B and <200 ppb for Mn, Ti and Ni (Supplementary) Table 1). Values that were within 1σ of the detection limit were excluded during data reduction. 238 Data reported in Tables 1, 2, 3 are single-spot analyses, whereas averages of trace element 239 240 compositions in olivine for each sample (data in Figures 6 and 7) are reported in Supplementary 241 Table 2). Supplementary Table 3 reports 1σ error values of olivine analyses reported in Table 1. A typical time series for the analysis of trace elements in olivine is reported in the Supplementary 242 243 Note 1. Instrument sensitivity due to analytical conditions was determined from the average across 244 all days of repeat measurements of the synthetic NIST 612 glass (Pearce et al., 1997). Sensitivities 245 were 800 cps/ppm for Ni, 2000-4000 cps/ppm for Ti, B and Zn, 6000-15000 cps/ppm for Li, Cu, 246 Sb, Ba, Nd, Sm, Gd, Dy, Yb and Pb and >20000 cps/ppm for all other elements. Precision and 247 accuracy were constrained by 8 analyses of reference basalt BIR 1-G (Supplementary Table 1): 248 reproducibility was better than 5% for most elements except for Pb (16%), B and Ta (<10%) and 249 measured values were comparable within analytical uncertainties to GEOREM accepted values 250 (Jochum et al., 2005).

251

252 4. MAJOR AND TRACE ELEMENT MINERAL CHEMISTRY

253 Major and trace element compositions of olivine, plagioclase, clinopyroxene and 254 orthopyroxene are shown in Tables 1, 2, 3. In most analysed olivines, we observed acceptable 255 correlations between the Ni, Mn and Ca abundances analysed by EPMA and LA-ICPMS (see 256 Supplementary Figure 1). Overall, the major and trace element chemistry data that are reported here for clinopyroxene and plagioclase in samples MF22, MF40, MF21, MF51 are similar to previously
published datasets (Borghini et al., 2007).

259

260 **4.1. Peridotites**

Olivines in peridotites have forsterite contents ranging Fo₈₉-Fo₉₀. They display the highest 261 Ni (2570-2725 ppm) coupled to the lowest Mn (1170-1210 ppm), Zn (56-61 ppm), Hf, Ti and Li 262 263 abundances, of all investigated (peridotite-troctolite-gabbro) samples (Figs. 4, 5, 6). REE patterns 264 define regular trends for the H- (heavy) REE, but tend to be more disperse for the M- (middle) and 265 especially the L- (light) REE (Fig.7). They show strong MREE/HREE fractionation ($Tb_N/Yb_N =$ 266 0.004-0.042, normalized to C1-chondrite of Sun and McDonough, 1989), more pronounced than in 267 the majority of available literature data on trace element chemistry of mantle olivines in orogenic 268 massifs and xenoliths (see compositional field and references reported in Figure 7). However, 269 published data mostly refer to metasomatized peridotites, as indicated by their enrichment in LREE 270 and other highly incompatible elements (see fields in Figures 7c, 8c). Note also that all previous 271 data are bulk analyses of olivine separates, thus possibly incorporating trace elements hosted in 272 inclusions. On the other hand, D'Errico et al., 2015 recently documented similar MREE/HREE 273 fractionation in olivine from Gakkel Ridge peridotites (see the compositional field in Figures 7c, 274 8c).

275 Plagioclase in peridotites is fully replaced by low-grade alteration products. Clinopyroxenes 276 are partly dissolved and replaced by (orthopyroxene + plagioclase) intergrowths crystallized from 277 the infiltrating melts. Their major and trace element compositions (Figs. 7,8 and Table 3) are 278 consistent with previously published data (Borghini et al., 2007). Melt-rock interaction has 279 modified their trace element composition (Borghini et al., 2007), causing an overall REE increase 280 (M- to H-REE up to > 10xC1, see Fig. 7a), coupled to Zr, Y, Sc, V enrichment and strong Sr 281 depletion (see Fig. 8a), compared to clinopyroxenes in those Erro-Tobbio spinel peridotites that 282 represent the mantle protolith before melt impregnation (Rampone et al., 2004; 2005). Similar 283 changes in clinopyroxene composition have been largely documented in plagioclase-rich 284 impregnated peridotites of the Alpine-Apennine system (Rampone et al., 1997, 2008; Piccardo et al., 2004; Zanetti et al., 2007). They are interpreted as resulting from the combined effects of 285 286 equilibration with enriched melts modified during reactive percolation at decreasing melt mass, and 287 crystallization of small trapped melt fractions. In spite of the overall REE increase, clinopyroxenes 288 preserve marked LREE depletion ($La_N/Yb_N = 0.008-0.016$), more pronounced than in 289 clinopyroxenes from troctolites and gabbros (see Figure 7a). On this basis, Borghini et al. (2007) 290 and Rampone and Borghini (2008) inferred that melt impregnation in the Erro-Tobbio peridotites was caused by reactive porous flow of orthopyroxene-saturated depleted MORB-type melts,unrelated to subsequent intrusion of N-MORB-type magmas.

The analyzed orthopyroxenes represent melt-rock reaction products, crystallized together with plagioclase and replacing mantle clinopyroxene (see description above). They display low REE abundances (M-, H-REE below 2-3x C1, Fig. 7a), significant LREE/HREE fractionation ($Ce_N/Yb_N = 0.003-0.005$), and negative Sr and Eu anomalies coupled to Zr and Hf enrichment relative to the neighbouring REE (Fig. 8a).

298

299 **4.2. Troctolites and Gabbro**

300 Olivines from troctolites have high forsterite contents (Fo₈₈-Fo₈₉). The lowest forsterite 301 values (Fo₈₈) are observed in samples with variable (granular and harrisitic) texture. They also 302 display relatively high Ni (2050-2280 ppm), Mn (1010-1625 ppm) and moderate Zn (45-70 ppm) 303 contents (see Fig. 4,5). The Co abundances are more scattered, and similar to those of olivines in 304 peridotites. Troctolite olivines display a negative correlation between Mg# (Mg/(Mg+Fe)) and Mn content (Fig. 4b), with the lowest Mg# and highest Mn values observed in the composite granular-305 306 harrisitic samples. As expected, olivines in gabbro MF22 have the lowest forsterite contents (Fo₈₃-307 Fo₈₄), combined with the lowest Ni (1355-1415 ppm) and higher Mn (1890-1970 ppm), Zn (93-102 308 ppm) and Co (165-170 ppm) abundances. For all these elements (i.e. Mn, Zn, Co, Ni), troctolite 309 olivines show intermediate concentrations compared to those of olivines in peridotites and gabbro. 310 In contrast, their Hf, Ti and Zr concentrations are more variable (progressive enrichment), and 311 extend beyond those of olivines in the gabbro (Figs. 6,7). Li abundances show the same behaviour, 312 although the data are slightly more scattered (see Fig. 6d). Olivines in troctolites also exhibit the 313 highest REE contents (HREE up to 0.8-1xC1, Fig. 7c), coupled to strong MREE/HREE 314 fractionation ($Tb_N/Yb_N = 0.004-0.042$) and development of significant positive Zr-Hf anomalies 315 relative to the neighbouring REE (Fig. 8c). Drouin et al. (2009) documented similar REE 316 compositions in olivine from Mid Atlantic Ridge (MAR) olivine-rich troctolites (see the grey field 317 in Fig. 8c).

Plagioclases in the studied troctolites and gabbro have similar anorthite contents (An₅₈₋₆₃ in troctolites, An₆₂ in gabbro, see Table 2). In the troctolites, the lowest anorthite values (An₅₈₋₅₉) are observed in composite granular-harrisite samples. Overall, plagioclases display LREE-enriched REE patterns (La_N/Sm_N = 1.23-2.56, Fig. 7a), positive Sr and Eu anomalies, and strong negative Zr-Hf anomalies relative to the neighbouring REE (Fig. 8b). In gabbro MF22, plagioclases exhibit the lowest REE abundances (LREE < 1 x C1), whereas in troctolites they show a larger LREE variability, with LREE up to 4xC1 in plagioclases of composite granular-harrisite troctolites (Fig. 325 7a). Similar REE compositions were documented by Borghini et al. (2007) (see the grey field in326 Fig. 7b).

The major and trace element compositions of clinopyroxenes reported in Table 3 were 327 328 measured in cores of large crystals. For the purpose of this study, we did not consider within-crystal 329 major-trace element variations related to late-stage crystallization of interstitial trapped melts. The 330 reader can refer to Borghini and Rampone (2007) for this specific issue. Troctolite clinopyroxenes 331 have high Mg# (0.89-0.90) coupled to relatively Al₂O₃ (3.04-4.82 wt%), Na₂O (0.43-0.61 wt%) and 332 Cr_2O_3 (1.02-1.50 wt%) concentrations (Table 3), similar to those of clinopyroxenes from oceanic and ophiolitic troctolites (Drouin et al., 2009; Sanfilippo and Tribuzio, 2012). Lower Mg# (0.86) 333 334 and Al₂O₃, Cr₂O₃ contents are found in clinopyroxenes of gabbro MF22. Overall, clinopyroxenes 335 display moderate LREE depletion ($La_N/Sm_N = 0.11-0.14$ in troctolites and gabbro) and almost flat 336 MREE to HREE patterns. As described above for plagioclase, gabbro clinopyroxenes have the 337 lowest REE abundances (M-H-REE below 10 x C1, Fig.7a), whereas troctolite clinopyroxenes 338 exhibit a general REE increase (M-H-REE up to 20 x C1) at nearly constant LREE fractionation 339 (Fig. 7a). The REE increase is coupled to the development of negative Eu and Sr anomalies relative 340 to neighbouring REE (Fig. 8a).

341

342 **5. DISCUSSION**

343 **5.1. Mineral/mineral REE partitioning**

344 A number of studies have shown that the distribution of trace elements between olivine, 345 orthopyroxene and clinopyroxene depends on temperature, pressure and mineral compositions (e.g. 346 Witt-Eickschen et al., 2005; Lee et al., 2007; Sun and Liang, 2012, 2013, 2014). For REE, the effect 347 of decreasing temperature is to redistribute these elements into clinopyroxene, thus lowering the 348 olivine/clinopyroxene and orthopyroxene/clinopyroxene partition coefficients. Also, this effect is stronger for the LREE relative to the HREE, possibly resulting in significant changes of the 349 350 LREE/HREE fractionation in low-T (< 1000 °C) re-equilibrated minerals (Sun and Liang, 2014). 351 Lee et al. (2007) predicted Ol/Cpx and Opx/Cpx REE partition coefficients at variable 352 temperatures based on lattice strain theory. Sun and Liang (2014) developed parameterized lattice 353 strain models for REE and Y distribution among mantle minerals in a wide range of T conditions 354 (800-1300°C), using mineral/melt partitioning models calibrated against experimentally determined mineral/melt partition coefficients (Sun and Liang, 2012, 2013). In order to test the distribution of 355 356 REE between olivine, clinopyroxene and orthopyroxene in the Erro-Tobbio peridotites, troctolites and gabbro, and derive information about equilibration temperatures, we computed Ol/Cpx and 357 358 Opx/Cpx REE partition coefficients in our samples, and compared them with i) predicted trends by

359 Lee et al. (2007) (Fig. 9), ii) computed olivine/cpx trends, according to Sun and Liang (2012, 2013,

360 2014) modeling. This approach allows to calculate Ol/Cpx partition coefficients at varying T for a 361 specific sample, using proper major element mineral compositions (Fig. 10; see figure caption for 362 more details). The two sets of modelled temperature contours, shown in Figures 9 and 10, are 363 similar, with a modest shift at higher Ol/Cpx partitioning values, at a given T, of trends computed

according to Sun and Liang (2014) (see Figs. 9a and 10).

365 In all samples, Ol/Cpx partition coefficients regularly decrease from Lu to Dy, whereas they 366 tend to define concave trends from MREE to LREE (Figs. 9a, 10). Similar "U-shaped" Ol/Cpx 367 partitioning was already documented in previous studies (e.g. Agranier and Lee, 2007; Lee et al., 2007) and was ascribed to the difficulty to get accurate analyses of LREE in olivine, due to the 368 369 extremely low concentrations in these elements, and/or to the occurrence of LREE-bearing fluid 370 inclusions. However, it is remarkable that the Ol/Cpx partition coefficients for Gd, Eu and Nd in 371 most samples are consistent with predicted trends (see Figs. 9a and 10), pointing to the reliability of 372 our olivine data set for the majority of REE. Overall, the Ol/Cpx H- to M-REE distribution in most 373 investigated samples defines arrays that are slightly steeper than computed trends. As already 374 outlined in the results section, this is likely a consequence of the strong MREE/HREE fractionation 375 shown by olivines in this study, more pronounced than the large majority of published data. Except 376 for Dy and Tb, most Ol/Cpx partitioning data for the HREE indicate rather high equilibration 377 temperatures (> 1100 °C). The highest values are observed in the troctolites, relative to peridotites 378 and gabbro, and are probably related to the high HREE concentrations in olivines of troctolites 379 resulting from melt/rock reaction processes (see the discussion below)

In Figure 9b, we also show the Opx/Cpx REE distribution coefficients for the two peridotite samples, compared with modelled trends by Lee et al. (2007). They define almost linear arrays, monotonically decreasing from HREE to LREE. Remarkably, these trends are mostly consistent with predicted Opx/Cpx partitioning at high temperature (> 1300 °C). In these samples, high-T estimates (1350-1400 °C) were also obtained by the REE in two-pyroxene thermometer of Liang et al (2013).

In summary, mineral/mineral REE partitioning in the Erro-Tobbio samples are mostly indicative of high temperature of equilibration (> 1100-1200 °C). Accordingly, we infer that the REE concentrations in olivine, clinopyroxene and orthopyroxene were not significantly modified by subsolidus re-equilibration, hence potentially recording information about the chemical signature of equilibrium melts. Nevertheless, the possible effect of decreasing temperature on olivine/clinopyroxene REE re-distribution is further discussed in the following section.

392

393 **5.2.** Paradoxical chemical signatures in olivine

The comparison of olivine compositions in the three investigated rock types, peridotite, troctolite and gabbro reveals both expected and unexpected behaviour for trace elements.

Remarkably, olivines in the three rock types exhibit distinct geochemical signature and define systematic elemental correlations for a series of minor (Ni, Mn) and trace elements (Zn, Co, Ti, Zr, Hf, HREE). Similar correlations (at least for Ni, Mn, Ti, Zr, Yb) have been documented by Sanfilippo et al. (2013) in a study of troctolites and mantle peridotites from the Alpine ophiolites (see data reported in Figs. 4,5,6). These data provide the evidence that olivine, although being a very minor reservoir for many trace elements, can record magmatic processes.

402 As expected, highly compatible elements in olivine such as Ni (Lee et al., 2007; Spandler et 403 al., 2010, and references therein) show the highest contents in peridotite, intermediate in troctolite 404 and lowest in gabbro, whereas Mn, Zn and Co show the opposite behaviour. Data on the 405 partitioning of Mn, Zn and Co in olivine (Ehlers et al., 1992; Kennedy et al., 1993; Beattie, 1994; 406 Gaetani and Grove, 1997; Kohn and Schofield, 1994; Bedard, 2005; Mysen, 2007; Spandler and 407 O'Neill, 2010) indicate a moderately incompatible to compatible behaviour. De Hoog et al. (2010), 408 in a comprehensive study of the trace element composition of mantle olivines from different origins 409 and settings, found negative correlations between Mn, Zn abundances and forsterite contents, thus 410 confirming their moderately incompatible behaviour. They also documented little systematic variation of Co with forsterite values, indicative of a $K_D^{ol/melt}$ very close to 1. In our study, the 411 412 overall increase of Mn, Zn and Co abundances in olivines from mantle peridotites to gabbro further 413 demonstrate a moderately incompatible behaviour of these elements. Moreover, in the Mg# versus 414 Ni diagram of Figure 4a, the compositional array defined by the Erro-Tobbio peridotite-troctolite-415 gabbro olivines is roughly consistent with computed trends for fractional crystallization at low 416 pressure (< 5 Kb) of a primary MORB melt (e.g. Drouin et al., 2009; grey lines in Fig. 4a). In 417 addition, Mn and Ni abundances of troctolite olivines fall within the compositional field defined by 418 MORB phenocrysts (see Figs. 4a,b; data from Sobolev et al., 2007). These features are in agreement 419 with previous inference by Borghini et al. (2007) that troctolites and gabbros reflect crystallization 420 products of variably evolved MORB magmas.

421 Zr, Hf, Ti and HREE display unforeseen behaviours. The concentrations of these elements 422 in troctolite olivines define enrichment trends that start from abundances similar to those in gabbro 423 olivines, and go up to one order of magnitude higher values (Fig. 6). These elements are all highly 424 incompatible in olivine (Lee et al., 2007; Spandler and O'Neill, 2010; De Hoog et al., 2010; and 425 references therein). If the composition of olivine in troctolites and gabbros were simply reflecting 426 fractionation from a variably evolved melt, we would expect the highest contents in incompatible 427 elements in the gabbro olivines. Moreover, the HREE enrichment in troctolite olivine is coupled to 428 the development of pronounced Zr-Hf positive anomalies and Zr/Nd fractionation (Zr_N/Nd_N up to 429 100). The same selective Zr-Hf enrichment was described in olivines from oceanic troctolites by 430 Drouin et al. (2009). All these features indicate that the behaviour of these elements in the studied 431 olivine data set does not conform to a simple magmatic crystallization process, and melt/rock 432 reaction processes likely have occurred (see the discussion section below).

Another unexpected chemical characteristic in olivine is its ubiquitous (even in the gabbro) depleted REE composition (Fig. 7c). Similar REE patterns were documented by Drouin et al. (2009) in olivines from oceanic troctolites. These authors observed that computed melts in equilibrium with such olivines are significantly more depleted than melts in equilibrium with associated plagioclase and clinopyroxene. Hence, they proposed that the trace element depleted signature of olivine in the troctolites could reflect a mantle origin, whereas plagioclase and clinopyroxene crystallized from impregnating MORB-type melts.

440 The REE composition of melts computed in equilibrium with olivine, clinopyroxene, orthopyroxene and plagioclase from the Erro-Tobbio peridotites, troctolites and gabbro are shown 441 in Figure 11. Following Drouin et al. (2009), melts were computed using clinopyroxene/liquid, 442 443 orthopyroxene/liquid, and olivine/liquid partition coefficients from Lee et al. (2007), and 444 plagioclase/liquid partition coefficients from Aigner-Torres et al. (2007). As previously documented 445 by Drouin et al. (2009), computed melts in equilibrium with olivine in all investigated lithotypes 446 exhibit lower REE abundances than melts in equilibrium with clinopyroxene. An exception to this 447 behaviour is provided by Yb, which shows similar values in most computed melts (Fig. 11a,b,c). In 448 troctolites, melts in equilibrium with plagioclase and clinopyroxenes display large variation in 449 absolute REE contents, related to late-stage crystallization of interstitial melts (Borghini and 450 Rampone, 2007). In spite of such variation, computed melts exhibit similar composition, with 451 nearly flat REE patterns, indicative of a MORB affinity (Borghini et al., 2007). In contrast, melts in 452 equilibrium with olivine display strong MREE/HREE fractionation ($Dy_N/Yb_N = 0.17-0.39$). 453 Although such decoupling in the troctolites could reflect a different origin between olivine (possibly 454 mantle derived) and associated plagioclase/clinopyroxene, this can be ruled out in gabbro MF22 (Fig. 11c), for which microstructural and major-minor element chemical features of olivine (and 455 456 field relations) clearly indicate a magmatic origin.

In order to test whether the adopted partition coefficients could have a role in generating such contrasting signature, we also calculated the equilibrium melts using the following sets of partition coefficients: i) the compilation proposed in Bedard (2001), derived on the basis of empirical relationships between ln(Kd) and composition, and adopted by Lissenberg et al. (2013) to model reactive melt migration in the lower oceanic crust of Hess Deep (EPR), ii) the olivine/melt and clinopyroxene/melt partition coefficients computed for our samples at T = 1200 °C, according to Sun and Liang (2012, 2013) mineral/melt REE partitioning models. The resulting REE 464 compositions of equilibrium melts are reported in Figures 12 and 13. In spite of differences in 465 absolute concentrations, we observed the same decoupling between the M-H-REE composition of melts in equilibrium with plagioclase and clinopyroxene, and those in equilibrium with olivine, the 466 467 latter being even more fractionated $(Dy_N/Yb_N = 0.043-0.098)$ when using the Bedard (2001) Kds. 468 Finally, in order to check whether the observed decoupling of equilibrium melts compositions could be related to subsolidus redistribution of REE between olivine and clinopyroxene at lower 469 470 temperature, we computed apparent melt compositions using the Kds sets obtained at 1100°C, by using Sun and Liang (2012,2013) models. The results are shown in Supplementary Figure 2. Again, 471 472 the major effect is a difference in absolute concentrations, with a general shift at lower REE 473 contents of computed melts in equilibrium with clinopyroxene, and higher REE abundances of 474 computed melts in equilibrium with olivine. On the other hand, the decoupling of M-H-REE composition in clinopyroxene and olivine equilibrium melts largely persists, although the latter are 475 476 slightly less fractionated ($Dy_N/Yb_N = 0.13-0.29$ at 1200°C, and 0.15-0.34 at 1100 °C). Therefore, 477 re-distribution of REE between olivine and other minerals at subsolidus conditions is not sufficient 478 to explain the observed decoupling.

- A robust explanation of such chemical discrepancies between melts computed in equilibrium with olivine and those in equilibrium with all other minerals is presently lacking, and possibly lies in the inhibited incorporation of REE into the olivine crystal lattice, due to their high ionic radius relative to the M1 and M2 sites dimensions (Zanetti et al., 2004; Foley et al., 2013). This, in turn, can explain the uncertainties and variability of available partition and diffusion coefficients for REE and other highly incompatible elements in olivine.
- 485 Available experimental studies on the diffusion of trace elements in olivine have provided 486 contrasting results. Spandler et al. (2007) and Spandler and O'Neill (2010) documented fast re-487 equilibration of REE in olivine, at rates similar to Mg-Fe exchange. By contrast, Cherniak (2010) 488 and Remmert et al. (2008) found much lower (more than three order of magnitude) REE diffusion 489 coefficients. They showed that REE diffusion in olivine is faster than in orthopyroxene and 490 clinopyroxene, but slow enough to preserve REE heterogeneities in melt inclusions in olivine 491 phenocrysts, at time scales of geologic processes. Cherniak (2010) also documented similar 492 diffusivities for M- and H-REE (La, Dy, Yb), indicating no correlation between REE diffusion 493 coefficients and ionic radius (consistent with Spandler and O'Neill, 2010), and little dependence of 494 REE diffusion rates on crystallographic orientation. This behaviour differs from the pronounced 495 anisotropy (more rapid diffusion parallel to c axis) documented for Fe-Mg and many trace elements 496 (e.g. Ni, Cr, Zr, Hf) in olivine (Chakraborty, 1997; Petry et al., 2004; Ito and Ganguly, 2006; 497 Spandler and O'Neill, 2010; Jollands et al., 2014).

498 More recently, Burgess and Cooper (2013) explained the discrepancies between the results 499 of Cherniak (2010) and Spandler and O'Neill (2010) as a consequence of different diffusion 500 mechanisms acting in olivine, with "lattice diffusion" in the former, and "fast-path diffusion" 501 promoted by formation of extended defects, in the latter. Specifically, Burgess and Cooper (2013), 502 in a combined experimental-TEM study on olivine in equilibrium with a TiO_2 -rich MORB (similar 503 to that used by Spandler and O'Neill, 2010), showed that the nucleation and growth of planar 504 defects in olivine is enhanced by large TiO₂ chemical potential gradients at the olivine-melt boundary (leading to substitution of Ti⁴⁺ for divalent cations in the olivine octahedral site, and 505 formation of octahedral vacancies). These authors outlined the need for a re-evaluation of the 506 507 "simple" lattice diffusion mechanism, especially in the case of natural reacting systems governed by 508 significant chemical potential gradients (e.g. metasomatism or magma mixing), and the importance 509 of detailed analysis of natural and experimental samples for a better understanding of trace element 510 diffusion in olivine.

511 In spite of such contrasting results, all studies provide consistent evidence of similar 512 diffusion coefficients in olivine from HREE to LREE. Therefore, the ubiquitous strong 513 MREE/HREE fractionation observed in all the analysed olivines cannot be easily related to 514 modifications of the REE profile acquired by subsolidus diffusion and re-equilibration, as a 515 consequence of different M- to H-REE diffusion rates. On the other hand, the large variation of 516 available partition coefficients for REE (one to two orders of magnitude, especially for the LREE 517 and MREE; see Bedard, 2001; Lee et al., 2007; Spandler and O'Neill, 2010) indicates the difficulty 518 to get reliable values, and sheds light on the caution that is needed in using olivine REE contents to 519 derive information about the compositions of equilibrum melts. The main factors influencing the 520 REE partitioning between olivine and melt have been discussed in a series of papers. Bedard (2005) examined published natural and experimental olivine/liquid D, and found a general tendency to increase 521 522 with decreasing temperature and MgO content in the melt. Evans et al. (2008), in an experimental 523 study in the CMAS system, documented strong inverse correlation between olivine-melt partition 524 coefficients and SiO₂ contents in melt. Finally, Sun and Liang (2013), through the development of 525 parameterized lattice strain models, found that the primary variables determining the REE and Y 526 partitioning between olivine and melt are pressure, Forsterite and Al contents in olivine.

527 Overall, the results of our study further emphasize the need of enlarging the trace element 528 olivine data set in natural mantle and gabbroic samples, as well as the importance of parallel 529 experimental work. Based on present knowledge, the REE composition of olivine cannot be easily 530 adopted to discriminate between mantle versus magmatic origin. Nevertheless, the peculiar and 531 systematic trace element signature documented in olivine of troctolites points to a more complex 532 origin than a simple fractional crystallization.

534 **5.3.** Evidence of melt/rock reaction in troctolites

535 The studied troctolites show microstructural and chemical evidence of mineral/melt reaction 536 and disequilibrium. In most samples, olivine displays irregular and lobate contacts against 537 interstitial minerals (plagioclase and subordinate clinopyroxene) indicative of reactive dissolution 538 and resorbtion. Reactive dissolution of olivine is even more evident in coarse-grained harrisitic 539 troctolites (e.g. sample MF72Ha), where centimetre-size hopper olivine crystals are significantly 540 corroded by plagioclase crystallization (Fig. 3c). Similar granular to hopper to harrisitic textures in 541 olivine are described in the literature in layered intrusions and ophiolites (e.g. Donaldson et al., 542 1982; O'Driscoll et al., 2007; Renna and Tribuzio, 2011), and are considered to result from open-543 system processes causing variations in melt composition and, consequently, in the degree of 544 undercooling (e.g. Faure et al., 2003). Moreover, in the troctolite apophysis MF51 olivine occurs 545 both as euhedral crystals and as large and irregular kinked grains, partly resorbed by plagioclase 546 (Fig. 3b). All these features point to disequilibrium and reaction between the olivine framework (at 547 least part of it) and the melt that crystallized the interstitial minerals.

548 Specific chemical characteristics also provide the same information. As outlined by 549 Borghini et al. (2007), the overall major element compositions of minerals in Erro-Tobbio 550 troctolites and gabbros define a variational trend at rather low An contents in plagioclase at given 551 Fo in olivine and Mg# of clinopyroxene, as observed in some gabbroic rock suites from the Mid-552 Atlantic Ridge (e.g. Ross and Elton, 1997). Troctolites, specifically, display variable An contents in 553 plagioclase at rather constant Fo value in olivine. The new troctolite samples analysed in this study 554 with granular to harrisitic textures further confirm the lack of Fo-An correlation in the troctolites, 555 being characterized by very low An values in plagioclase (An₅₈₋₅₉) at high Fo contents in olivine 556 (Fo_{87.5-88.5}) and high Mg# in clinopyroxene (100*Mg# = 88-89.8)(see Tables 1,2,3). Although part 557 of such chemical features, namely the low An contents in plagioclase and high Mg# in 558 clinopyroxene, can be ascribed to crystallization at moderate P conditions (3-5 kbar, see Borghini et 559 al., 2007), the large compositional range defined by plagioclase in the troctolites (An₅₈₋₆₆; Borghini 560 et al 2007 and this study) at rather constant olivine composition rules out a simple process of 561 fractional crystallization. This in turn calls for melt-rock reaction processes, in which exotic input of 562 more evolved melts in a previously crystallized olivine framework, and/or crystallization of 563 intercumulus liquid evolving upon cooling and partially trapped within the crystal mush, could have 564 played a role.

565 Both textural and mineral chemistry features in the Erro-Tobbio troctolites thus point to 566 melt-rock reaction involving olivine dissolution and concomitant plagioclase crystallization. In 567 order to test, with a simple but effective approach, whether the observed trace element variations and geochemical signature in olivine of troctolites, namely the selective HFSE (Zr, Hf, Ti) and
HREE enrichment, can be explained by such process, we performed an Assimilation Fractional
Crystallization (AFC) model (using the equation of De Paolo, 1981), assuming the following
reaction:

572

$olivine_1 + melt_1 = olivine_2 + plagioclase + melt_2$,

573 in which "olivine₂" represents the olivine reequilibrated with the reacted melt₂. For clarity, we 574 emphasize that in this study we were not able to distinguish two olivine generations in a specific 575 troctolite sample, both in terms of textural occurrence and chemical composition. We often 576 observed corroded olivine grains that texturally represent the "olivine₁" of the above reaction, but 577 possess geochemical characteristics of "olivine₂". We further discuss this point below.

578 The results of AFC modeling are shown in Figure 14, in terms of Zr_N/Nd_N versus Yb_N in 579 olivine computed in equilibrium with the reacted melt₂ (i.e. olivine₂). A major difficulty in 580 performing geochemical modeling is the choice of appropriate mineral/liquid partition coefficients. This is especially crucial in the case of olivine and plagioclase, for which complete mineral/liquid D sets 581 582 including REE and HFSE are poorly available in literature (see discussion above). We thus 583 performed two distinct AFC models (Models A and B of Fig.14a,b), keeping fixed all the 584 parameters except the partition coefficients, in order to highlight the variability of computed trends 585 resulting from the choice of D values. In both models, the assimilated mass (Ma) is equal to 100% olivine, whereas the crystallized mass (Mc) is 100% plagioclase. The composition of the starting 586 587 melt (C_0 , reacting with olivine₁) is equal to the melt computed in equilibrium with the troctolite 588 clinopyroxene showing the lowest REE concentrations (i.e. clinopyroxene in sample MF21; see 589 Figs. 7a, 8a). This melt is very similar (at least for the L- and M- REE) to the composition of melt 590 computed in equilibrium with troctolite plagioclase with the lowest REE abundances (i.e. 591 plagioclase in sample MF51, see Figs. 7b, 8b), and we considered it as the best proxy of the 592 composition of the interstitial melt before reactive crystallization. For the assimilated olivine, we 593 used the composition of olivine in peridotite MF40, showing the lowest Yb and HFSE 594 concentrations among all the investigated data set. It is remarkable, however, that olivine in gabbro 595 MF22 also show low Zr_N/Nd_N fractionation and REE (see Figs. 7c, 8c), being likely less affected by 596 melt-rock reaction processes than the troctolites. As clearly shown in Figure 14, the two (peridotite 597 and gabbro) olivine compositions almost overlap. Therefore, using the gabbro olivine as Ma would 598 have produced the same results discussed below.

599 Computed trends reported in Figure 14 show the compositions of olivine in equilibrium with 600 residual liquids (melt₂) at decreasing melt mass (F = 0.95-0.10). The four different trends refer to 601 different values of r (where r is equal to the Ma/Mc ratio). The models A and B (Fig. 14a,b) differ 602 only in terms of adopted partition coefficients (see figure caption for details and references). 603 Keeping in mind the uncertainties resulting from the adopted parameters (partition coefficients, 604 composition of initial melt C_0 and assimilated olivine Ma), and the very simplified approach, the 605 model clearly suggests that the observed enrichment in Zr in olivine of the troctolites can be 606 explained by a melt-rock reaction process involving dissolution of olivine and crystallization of 607 plagioclase (in almost equal amounts, best consistency with Ma/Mc = 0.95) at progressively decreasing melt mass. This is due to the fact that olivine has higher ^{mineral/liquid}D_{Zr,Hf} relative to 608 609 plagioclase, consistent with the significant Zr-Hf negative anomalies in plagioclase compositions, especially in plagioclase of gabbro MF22 (see Fig. 8b). This behaviour of olivine, i.e. olivine/liquid 610 D_{HFSE} > $^{olivine/liquid}$ D_{REE} , has been invoked by Kelemen et al. (1990) to explain the development of 611 612 arc-like signature in basaltic melt during reactive percolation through the lithospheric mantle, and it 613 has been confirmed by the study of Bedard (2005), who highlighted the ubiquitous presence of 614 positive D_{Ti,Zr,Hf} anomalies in experimental olivine/melt partitioning data for a wide range of 615 basaltic compositions.

616 As mentioned above, there is an apparent decoupling between the reaction considered in the 617 AFC model, and our textural and geochemical observations. The reaction involves an olivine₁, 618 likely possessing a higher forsterite content and low incompatible trace element abundances, and an 619 olivine₂, supposed to crystallized from the reacted melt. However, in our study troctolite olivines 620 which are significantly resorbed by plagioclase (i.e. texturally representing olivine₁), have enriched 621 trace element signature, i.e. that expected for olivine₂. This could be explained assuming that 622 olivine₁ has reset its composition, by interaction with the melt, rather than crystallizing in new 623 grains.

624 In this study, we aimed to provide a first trace element data set in olivine from associated 625 peridotite, troctolite and gabbro samples, in order to document major geochemical differences, if 626 any, between the different rock types, and test the potential of trace element chemistry in olivine to 627 track melt-rock reaction processes. Therefore, we did not focus the analytical work to detect within-628 grain elemental variations. The results of this study clearly indicate that the troctolites hold a more 629 complex magmatic history than previously documented (Borghini et al., 2007; Borghini and 630 Rampone, 2007). Borghini and Rampone (2007) found significant trace element zoning in poikilitic 631 clinopyroxenes, correlated with the microstructural site (e.g. core to rims of large crystals, to very 632 thin interstitial grains). They ascribed this feature to late-stage crystallization of interstitial trapped 633 melts, and assumed olivine dissolution to explain the development of positive Zr, Hf anomalies in 634 the very late-stage clinopyroxene. Here we show that olivine records the geochemical signature of 635 such melt-mineral reaction. Detailed microstructural and geochemical investigations, involving Crystallographic Preferred Orientation (CPO) analyses (e.g. Drouin et al., 2010) combined to 636 637 major-trace element traverses and mapping in selected olivine grains, will be essential to check the

existence of different generations of olivine within a single troctolite sample, and the preservation(or absence) of major, trace element zoning in a specific olivine crystal.

Records of compositional zoning in minerals largely depend on element diffusion rates, 640 temperature conditions of crystallization and cooling rates. Major and minor element variations in 641 642 olivine, such as decrease in NiO, Mg# and increase in TiO₂, have been documented in experiments of formation of plagioclase-bearing peridotites and wehrlites by reactive crystallization, and 643 644 ascribed to the effects of dissolution and reprecipitation from the basaltic melt (Saper and Liang, 645 2014). Moreover, Welsch et al. (2014) recently documented surprising dendritic zoning of 646 phosphorous in volcanic, experimental, and also plutonic olivine crystals (by electron probe microanalysis and mapping), and Burgess and Cooper (2013) shed lights on the diffusion 647 648 mechanisms in olivine by combined experimental and TEM investigations. Overall, these works 649 illustrate the usefulness of micro- and nano-scale detailed studies to get insights on combined 650 processes of olivine deformation, dissolution and growth. Textural and geochemical variability 651 documented in this study in troctolite olivines further confirms the relevance of such approaches.

652

653 6. CONCLUDING REMARKS

In-situ LA-ICP-MS analyses of a large set of trace elements in olivines of depleted mantle peridotites and associated primitive gabbroic rocks (troctolites and olivine gabbros) from the Ligurian ophiolites (Erro-Tobbio Unit, Italy) have revealed that olivines define systematic and reliable compositional trends that can be used to unravel their history of melt-rock reaction and magmatic crystallization.

659 In contrast with olivine gabbros, olivines in the troctolites display significant enrichment in 660 incompatible elements like Zr, Hf, Ti, HREE, coupled to development of significant HFSE/REE 661 fractionation. Such geochemical features are indicative of dissolution-precipitation processes and re-equilibration with reacted enriched melts. AFC modeling shows that the large Zr_N/Nd_N ratios in 662 663 olivines of troctolites are consistent with a process of olivine assimilation and plagioclase 664 crystallization at decreasing melt mass, in agreement with textural observations. Detailed in-situ 665 trace element geochemistry of olivine, possibly combined with focused microstructural analysis, 666 thus appears to be a powerful tool to investigate reactive percolation and the origin of olivine-rich 667 rocks in the lower oceanic crust.

668 Compositional contrasts between computed melts in equilibrium with olivine and coexisting 669 minerals, in both mantle peridotites and MORB-type gabbroic rocks, point to the need for a better 670 understanding of the mechanisms of incorporation and diffusion of trace elements in olivine.

671

672 ACKNOWLEDGEMENTS

We thank Andrea Risplendente (Dipartimento di Scienze della Terra, University of Milano) for his
assistance with the EPMA analyses, and Carlotta Ferrando (PhD student in Montpellier) who
performed part of the LA-ICP-MS analyses. J.C.M de Hoog and C. Sun are greatly acknowledged
for their constructive reviews. We also thank editorial advise and handling by W. van Westrenen

- and M. Norman. This study was supported by the University of Genova (grant PRA 2014), and the
 CNRS-INSU program SYSTER.

1126 FIGURE CAPTIONS

1127

Figure 1 – Sketch map of the Voltri Massif (VM), showing the Erro-Tobbio peridotite and surrounding units (redrawn after Federico et al., 2004): (1) Erro-Tobbio peridotite Unit (VM), (2) Calcschists and meta-volcanics (VM), (3) Serpentinites and metagabbros (VM), (4) Crystalline massifs, (5) Sestri-Voltaggio zone, (6) Flysch Units, (7) Post-orogenic and Tertiary Piedmont Basin deposits, (8) Montenotte Unit. The large red circle indicates the studied area. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article).

1135

Figure 2 – Field features of studied troctolites and gabbros. **a** Troctolite apophysis within mantle peridotites. **b** Textural variations (from granular to harrisitic types) within the troctolite. **c** Olivin gabbro dyke intruded (with sharp contacts) within the troctolite. **d** Close-up of Fig.2b, showing the textural variation of olivine (the dark grey mineral) from fine-grained granular (in the left bottom corner) to harrisitic-skeletal.

1141

Figure 3 – Microscopic textures of troctolites and gabbros (cross-polarized light). **a** Subidiomorphic rounded olivine grains (ol) surrounded by plagioclase (plag), in granular troctolite MF21; small black spinel grain (sp) included in plagioclase. **b** Large kinked olivine grain (kinked ol), with irregular lobate contacts against interstitial plagioclase, in troctolite apophysis MF51. **c** Large hopper-type olivine crystal (ol) with lobate resorbed contacts against interstitial plagioclase (plag) in troctolite MF73. **d** Subidiomorphic olivine grain surrounded by plagioclase crystals (in rather sharp contacts) in olivine gabbro MF22.

1149

Figure 4 – Variation of Mg# vs. Ni [a] and Mn [b] in olivines of Erro-Tobbio peridotites, troctolites and gabbro (see the legend for symbols). We also show olivine data for peridotites, dunites and troctolites in other Alpine-Apennine ophiolites (from Sanfilippo et al., 2014), together with the compositional field defined by olivine phenochrysts in MORB (data from Sobolev et al., 2007). Computed trends reported in Fig.4A refer to the compositional variations in olivine for fractional (FC) and equilibrium (EC) crystallization of a primary MORB melt at low pressure (< 5 Kb) (after Drouin et al., 2009).

Figure 5 – Variation of Mn vs. Ni [a], Co [b] and Zn [c] in olivines of Erro-Tobbio peridotites,
troctolites and gabbro. Also shown are peridotite, troctolite, ol-gabbro data from Sanfilippo et al.
(2014, 2015b).

1161

1157

Figure 6 - Variation of Zr vs. Hf [**a**], Ti [**b**], Yb [**c**] and Li [**d**] of olivines in Erro-Tobbio peridotites, troctolites and gabbro. In [**b**] and [**c**], we also reported peridotite-troctolite olivine data from Sanfilippo et al. (2014), and MAR troctolite olivine data from Drouin et al. (2009). The field refers to the compositional range defined by mantle olivines in orogenic massifs and xenoliths (see text for more explanation; data from Sun and Kerrick, 1995; Garrido et al., 2000; Bedini and Bodinier, 1999).

1168 Figure 7 - Chondrite-normalized Rare-Earth-Elements (REE) abundances of [a] clinopyroxene, 1169 1170 orthopyroxene, [b] plagioclase and [c] olivine of Erro-Tobbio peridotites, troctolites and gabbro (see the legend for symbols). The fields reported in [a] and [b] refer, respectively, to the 1171 1172 composition of clinopyroxene and plagioclase in ET troctolites from Borghini et al. (2007). In [c], we also show the compositional fields defined by: i) olivines in Mid-Atlantic Ridge troctolites 1173 1174 (Drouin et al., 2009); ii) mantle olivines in orogenic massifs and xenoliths (see text for more 1175 explanation; data from Sun and Kerrick, 1995; Eggins et al., 1998; Garrido et al., 2000; Gregoire et al., 2000; Bedini and Bodinier, 1999), iii) olivines in Gakkel Ridge peridotites (D'Errico et al., 1176 1177 2015). Normalizing values after Sun and McDonough (1989).

1179 Figure 8 – Primitive mantle-normalized trace elements abundances of [a] clinopyroxene, orthopyroxene, [b] plagioclase and [c] olivine of Erro-Tobbio peridotites, troctolites and gabbro 1180 1181 (see the legend for symbols). The field reported in [a] refers to the composition of clinopyroxene in 1182 ET troctolites from Borghini et al. (2007). In [c], we also show the compositional fields defined by: 1183 i) olivines in Mid-Atlantic Ridge troctolites (Drouin et al., 2009); ii) mantle olivines in orogenic 1184 massifs and xenoliths (see text for more explanation; data from Sun and Kerrick, 1995; Eggins et al., 1998; Garrido et al., 2000; Gregoire et al., 2000; Bedini and Bodinier, 1999), iii) olivines in 1185 Gakkel Ridge peridotites (D'Errico et al., 2015). Normalizing values after Sun and McDonough 1186 1187 (1989).

Figure 9 – [a] Olivine/cpx and [b] opx/cpx REE partition coefficients in the Erro-Tobbio
peridotites, troctolites and ol-gabbro. We also reported predicted ol/cpx and opx/cpx partitioning at
1000, 1300 and 1400°C, after Lee et al. (2007).

Figure 10 - Olivine/cpx REE partition coefficients plotted versus Ionic Radius in the Erro-Tobbio peridotites [a], troctolites and gabbro [b]. Also shown are olivine/cpx trends computed at varying temperatures (1000-1300°C) using the major element compositions of olivine and clinopyroxene in our samples (following the modelling procedure by Sun and Liang, 2012, 2013, 2014).

Figure 11 - Chondrite-normalized Rare-Earth-Elements (REE) abundances of computed melts in equilibrium with: [a] olivine, orthopyroxene and clinopyroxene in the peridotites, [b] olivine, clinopyroxene and plagioclase in troctolites, [c] olivine, clinopyroxene and plagioclase in gabbro (see the legend for symbols). Clinopyroxene/liquid, orthopyroxene/liquid and olivine/liquid partition coefficients are from Lee et al. (2007). Plagioclase/liquid partition coefficients are from Aignes-Torres et al. (2007). Normalizing values after Sun and McDonough (1989).

Figure 12 - Chondrite-normalized Rare-Earth-Elements (REE) abundances of computed melts in equilibrium with: [a] olivine, orthopyroxene and clinopyroxene in the peridotites, [b] olivine, clinopyroxene and plagioclase in troctolites, [c] olivine, clinopyroxene and plagioclase in gabbro (see the legend for symbols). Clinopyroxene/liquid, orthopyroxene/liquid, olivine/liquid and plagioclase/liquid partition coefficients are from Bedard (2001). Normalizing values after Sun and McDonough (1989).

Figure 13 – Chondrite-normalized Rare-Earth-Elements (REE) abundances of computed melts in equilibrium with: [a] olivine and clinopyroxene in the peridotites, [b] olivine and clinopyroxene in troctolites, [c] olivine and clinopyroxene in gabbro (see the legend for symbols).
Clinopyroxene/liquid and olivine/liquid partition coefficients at 1200 °C have been calculated following Sun and Liang (2012, 2013) models. Normalizing values after Sun and McDonough (1989).

1219 **Figure 14** – Variation of Zr_N/Nd_N ratio vs Yb_N in olivine of troctolites and gabbro, compared to olivine compositions computed by AFC model (De Paolo, 1981) at decreasing melt mass (F = 0.95-1220 0.10). The initial melt composition C_0 is equal to the melt computed in equilibrium with the 1221 clinopyroxene of troctolite MF21 showing the lowest REE concentrations (see Table 3). The model 1222 assumes that initial melt (melt₁) assimilate olivine (Ma = 100% olivine) and crystallize plagioclase 1223 1224 (Mc = 100% plag). The composition of assimilated olivine is olivine in peridotite MF40. The four 1225 different trends refer to different values of r (r = Ma/Mc). Model A in [**a**] and Model B in [**b**] differ 1226 only for the adopted partition coefficients. Model A: compilation of REE, Zr partition coefficients 1227 for olivine, plagioclase and clinopyroxene proposed by Suhr (1998). Model B: olivine/liquid D_{REE} by Lee (2007); olivine/liquid D_{Zr} by Spandler and O'Neill (2010); clinopyroxene/liquid D_{REE.Zr} by 1228 1229 Suhr (1998); plagioclase/liquid D_{REE.Zr} by Aignes-Torres et al., (2007).
